Abstract

The Dallol volcano and its associated hydrothermal field are located in a remote area of the northern Danakil Depression in Ethiopia, a region only recently appraised after decades of inaccessibility due to severe political instability and the absence of infrastructure. The region is notable for hosting environments at the very edge of natural physical-chemical extremities. It is surrounded by a wide, hyperarid salt plain and is one of the hottest (average annual temperature_{Dallol}: 36–38°C) and most acidic natural systems (pH_{Dallol} ≈ 0) on Earth. Spectacular geomorphologies and mineral deposits produced by supersaturated hydrothermal waters and brines are the result of complex interactions between active and inactive hydrothermal alteration of the bedrock, sulfuric hot springs and pools, fumaroles and geysers, and recrystallization processes driven by hydrothermal waters, degassing, and rapid evaporation.

The study of planetary field analog environments plays a crucial role in characterizing the physical and chemical boundaries within which life can exist on Earth and other planets. It is essential for the definition and assessment of the conditions of habitability on other planets, including the possibility for biosignature preservation and *in situ* testing of technologies for life detection. The Dallol area represents an excellent Mars analog environment given that the active volcanic environment, the associated diffuse hydrothermalism and hydrothermal alteration, and the vast acidic sulfate deposits are reminiscent of past hydrothermal activity on Mars. The work presented in this paper is an overview of the Dallol volcanic area and its hydrothermal field that integrates previous literature with observations and results obtained from field surveys and monitoring coupled with sample characterization. In so doing, we highlight its exceptional potential as a planetary field analog as well as a site for future astrobiological and exploration programs. Key Words: Hydrothermal systems—Extreme environments—Polyextremophiles—East Africa—Terrestrial analogs—Astrobiology—Planetary science. Astrobiology 19, 553–578.

1. Introduction

PROGRESS MADE in recent decades in the understanding of geological and biological planetary processes and their coevolution has shown that life may exist, and could have originated, in almost all the extreme environments that were considered detrimental to life in the recent past (*e.g.*, Brock, 1967; Rothschild and Mancinelli, 2001; Martin *et al.*, 2008).

Presently, microorganisms can be found in most natural and artificial (*e.g.*, acid mine drainage) extreme environments where liquid water and metabolically suitable carbon, energy, and nutrient sources exist. Living organisms tend to be sensitive to drastic changes in their environment, and their cellular integrity may be seriously compromised in extreme physical (*e.g.*, temperature, desiccation, radiation, and pressure) and (geo-)chemical (*e.g.*, salinity, pH, redox potential, or heavy metals) conditions. The microorganisms that live in the presence of such challenges are termed extremophiles and have physiologically adapted to live in and/or survive or tolerate these extreme and adverse environmental conditions.

The diversity and versatility of microbial metabolism combined with the extraordinary physiological capacities of many microorganisms to colonize any habitat suggest that a number of unrecognized terrestrial habitats probably exist. By analogy, this could also be true for other planetary bodies. Therefore, studying geological processes in extreme environments, together with habitability, plays a crucial role in determining the physical and chemical boundaries within which life can exist on Earth. In the comprehension of planetary landforms, in the assessment and definition of the criteria for habitability on other planets including the possibility for biosignature preservation (in their host matrix), for *in situ* testing of technologies and methodologies (*e.g.*, rovers and their payload), and for verifying laboratory methods and protocols for life-detection, such an approach provides valuable and critical information for future space missions (Amils *et al.*, 2007a; Baker, 2014; Martins *et al.*, 2017; Vago, 2017; Cavalazzi and Westall, 2019).

The Danakil (or Danakil) Depression in the northern part of the Afar Depression (also known as the Afar Triangle)

(Figs. 1 and 2), with its variety of extreme environmental conditions, intense seismicity, volcanism and associated hydrothermal activities, intermittent water flooding and sedimentary processes, is well known to geoscientists—for example, structural geologists, geophysicists, and volcanologists—as being part of the East African Rift System (Corti, 2009), an active continental rift system deforming a wide area between Djibouti and Mozambique (*e.g.*, McKenzie *et al.*, 1970; Ebinger and Casey, 2001; Tesfaye *et al.*, 2003; Beyene and Abdelsalam, 2005). It is also known for its (as yet not comprehensively estimated) natural resources that mostly comprise salt rocks such as potash, sulfur, manganese, bentonite, gold, and light and heavy hydrocarbon deposits, and for its promising geothermal energy sources (Allana Potash Corporation, 2011, 2012; Warren, 2016; Varet, 2018). The region is widely renowned among palaeoanthropologists due to its early hominid fossil finds including “Lucy,” the *Australopithecus afarensis* specimen discovered in 1974, dated at between 3.9 and 2.9 million years old (*e.g.*, Wood, 1994), and early human habitats. The Afar Region, in which a 4.4-million-year-old hominid named “Ardi” (*Ardipithecus ramidus*) was also discovered (White *et al.*, 1994), can be considered the place of origin of humankind. Finally, the region has been recently identified by astrobiologists as hosting the most diverse suite of extreme environments on Earth (Cavalazzi *et al.*, 2014).

Herein, we present (1) an updated overview of the Dallol (also rarely spelled Dalol) geothermal area, which is located in the Danakil Depression of the administrative Zone Two of the Afar National Regional State, in the northern part of Ethiopia (Fig. 1), integrating data from literature with observations and results obtained from field surveys and laboratory analysis, and (2) the enormous potential of the main site of the Dallol hot springs as a planetary field analog environment, highlighting its potential for astrobiological research. We also provide a brief examination of current advances concerning our understanding of the temperature-, pH- and salinity-resistant extremophilic microbes and their mechanisms of adaptation, and of the exploration of some examples of the extreme environmental conditions on Earth in which they are found.

FIG. 1. Location map of the study area. (A) The Dallol volcano is located in the northern part of the Afar Region in Ethiopia (black star; $14^{\circ}05'28.00''\text{N}$, $40^{\circ}17'58.00''\text{E}$). (B) Detail of the boxed area in (A) showing the directions of roads and tracks from the town of Berhale ($13^{\circ}51'46''\text{N}$, $40^{\circ}01'19.40''\text{E}$; 67 m a.s.l.) to the village of Hamed'Elä ($14^{\circ}05'06.00''\text{N}$, $40^{\circ}16'46.00''\text{E}$; 90 m b.s.l.) in the direction of the Dallol geothermal area. The Assale (or As'Ale, or Ashale) Ring ($14^{\circ}7'0.63''\text{N}$, $40^{\circ}20'52.59''\text{E}$), also known as Skating Ring, is a ~ 20 m high ring-structure, generated by a phreatic explosion, of reddish-gray evaporites and mud mixtures with a diameter of ~ 110 m which rises ~ 15 km south of the Dallol volcanic dome. The evaporites from Assale Ring, considered sacred by Afars, are used as traditional medicine.

FIG. 2. Simplified tectonic map of the triangular-shaped Afar Depression. The Dallol volcano (star) is located in the northern part of the Danakil Depression. Adapted from Tesfaye *et al.* (2003).

2. Geological Setting

The Dallol geothermal area is part of the Danakil Depression, which straddles the Ethiopia–Eritrea border, between the Ethiopian Plateau and the Danakil microplate (also called Danakil Alps or Mountains) in the northern part of the Afar Depression (Figs. 1 and 2).

The Afar Depression is an incipient seafloor-spreading center located at the triple junction between the Nubian, Somali, and Arabian plates, atop the developing Danakil microplate that is generating the continental breakup of Africa (*e.g.*, McKenzie *et al.*, 1970; Barberi *et al.*, 1972; Ebinger and Casey, 2001; Tesfaye *et al.*, 2003; Acocella, 2010; McClusky *et al.*, 2010) (Figs. 2 and 3). Here, the E-W ocean ridge spreading of the Gulf of Aden through Djibouti meets the axes of the Ethiopian Rift and the Red Sea (Fig. 3). McClusky *et al.* (2010) reported spreading rates of ~ 7 mm/year at the northern edge of the Afar Depression.

The Danakil Depression in the northern tectono-magmatic domains of the Afar Depression is a well-defined tectonic feature bordered both to the west and to the east by major faults and dissected escarpments (Figs. 2 and 3; Tesfaye *et al.*, 2003). The attenuated continental crust has a thickness of <15 km with shallow (3–5 km deep) magma chambers beneath its axial zones (Makris and Ginzburg, 1987; Maguire *et al.*, 2006; Wright *et al.*, 2006; Pagli *et al.*, 2012). The main volcano-tectonic features of these magmatic segments are intermittent NNW-SSE axial volcanic edifices and fissure

FIG. 3. Digital elevation map (SRTM data) of the Afar Depression, together with the Red Sea, Gulf of Aden, and Main Ethiopian (MER) rift zones (red lines) splitting apart the Arabian, Nubian, and Somali plates. NAD, CAD, SAD (separated by the yellow broken lines) are the northern, central and southern sectors of the Afar Depression (see Tesfaye *et al.*, 2003). The Dallol volcano (star) lies between the Danakil microplate and the Ethiopian plateau.

basalts, open extensional fractures and vertical step faulting (Figs. 4 and 5). The volcanic activity in this region has been intense since the Pliocene but is today mostly restricted to the axial zone with the spectacular shield and stratovolcanoes of the Erta' Ale Range (in the Afar language, 'Ale means mount), which include Ale Bagu, Erta' Ale, Borale' Ale, Dalafilla Alu, and other small volcanic and fumarolic centers (Barberi and Varet, 1971; Barrat *et al.*, 1998; Acocella, 2006; Ebinger *et al.*, 2008). Of the volcanic edifices that constitute the Erta' Ale Range, the Gada' Ale shield volcano and its surrounding fissural eruptions are part of the Dallol area (Fig. 4).

The magmatic and tectonic activity of the shield volcanoes of the Erta' Ale Range extends (NNW-SSE) to the Dallol area, and probably to the Gulf of Zula, as a continuous trending rift branch (Thurmond *et al.*, 2006). Satellite remote sensing and seismicity analyses have revealed the presence of a shallow dyke intrusion ($\sim 0.06 \text{ km}^3$) along the western flank of the Dallol segment fed by an 2.4 km deep active magma reservoir buried by evaporitic deposits beneath Dallol (Carniel *et al.*, 2010; Nobile *et al.*, 2012).

The Danakil Depression exhibits both oblique and orthogonal extensional tectonics, and fracture trace analysis has been deemed mandatory to outline the current condition of the axial rifts. In order to evaluate the Quaternary kinematics and geometry of the Dallol Depression, rift axis fracture data have been collected from the fissural basalts of the area. Structural data presented herein were acquired during field campaigns and combined with data from geological mapping and processed Landsat-8 ETM+ images, as the area is difficult to access (Fig. 5). The area includes various structures, such as extensional fractures, elliptical caldera collapses of various sizes, cinder cones, and in some places normal faults with throws not exceeding 10 m. For understanding the kinematics of the Dallol Depression, only the young extensional fractures were analyzed using stereo plots (see Acocella and Korme, 2002).

A total of ~ 50 fracture orientations, from both the field survey and Landsat image, and 10 asperities were measured from the fissural and shield basalts of the Gada' Ale volcano (Fig. 5). All measured open fractures have an opening between 0.05 and 1 m and a length between 3 and 100 m; their

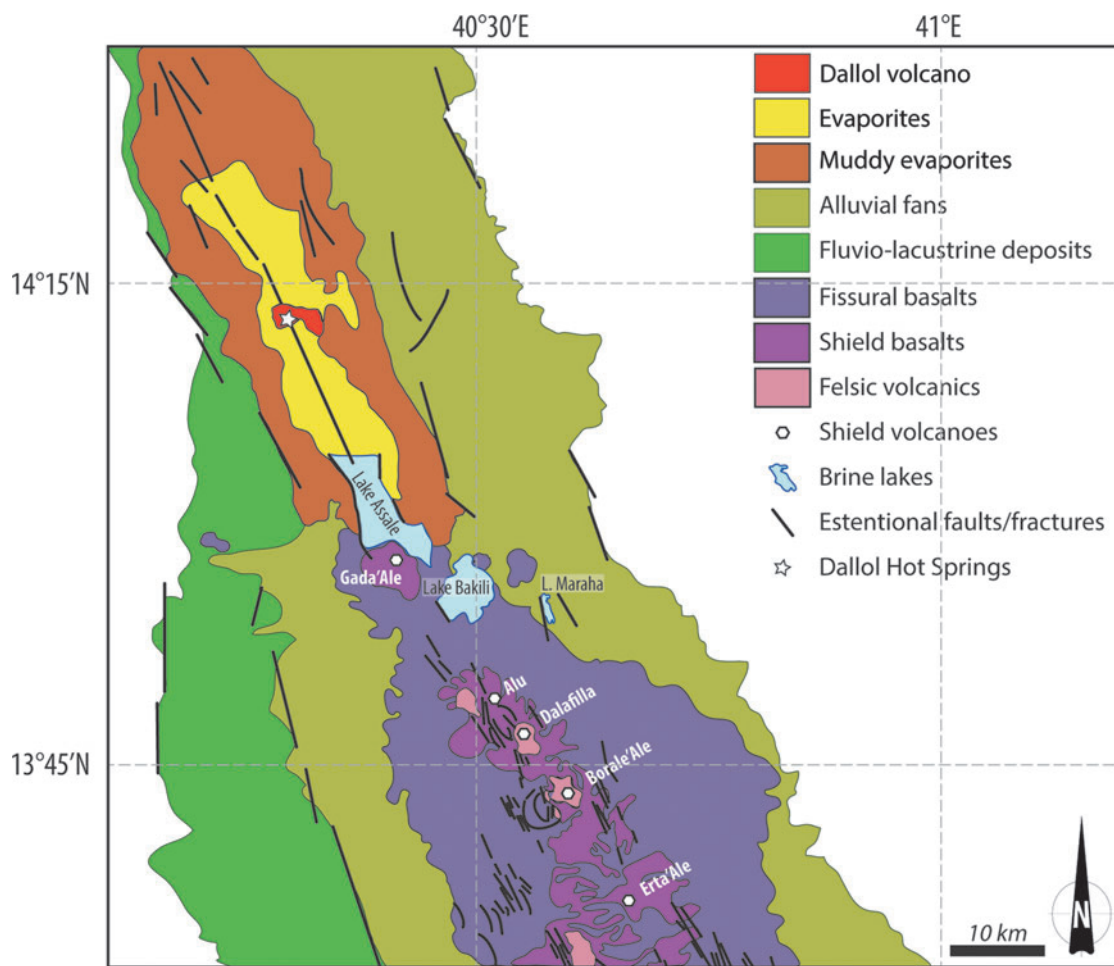

FIG. 4. Simplified geological and structural map of the north-central part of the Danakil Depression, which includes the Dallol volcano and its hydrothermal system (star), the Assale salt plain (evaporites) and the Erta'Ale Range (volcanics). Lithological and structural contacts were obtained from Landsat ETM +2002 bands 7, 5, and 2 and confirmed by field mapping.

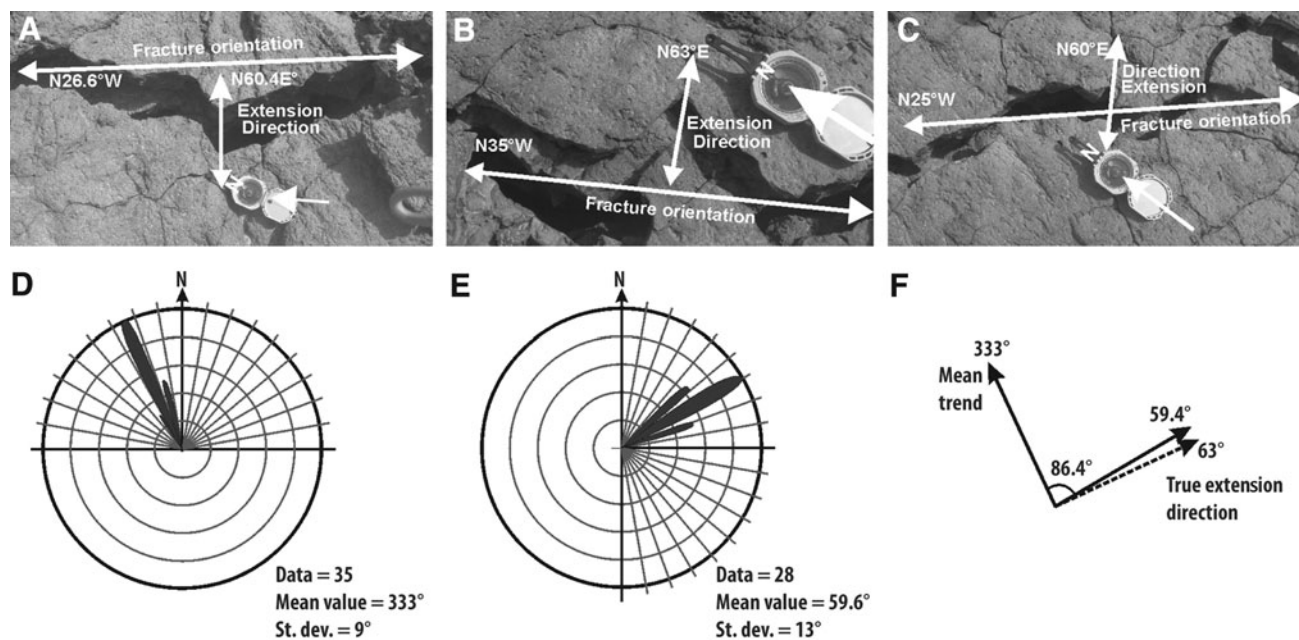

FIG. 5. Representative photographs of extensional fractures (A–C) and their average orientation (D) and mean opening direction (E) within the Dallol geothermal area, northern Danakil Depression. (F) The 86.4° angle between the fracture trend and extension direction suggests a nearly orthogonal extension. The compass is 7 cm in diameter.

depth of penetration, ~ 700 m, is inferred from mechanical considerations (Acocella and Korme, 2002). The features representing the convergence of the two fractures are surfaces represented by asperities, which were sharp, fresh, and unaffected by surface processes and other secondary deformation, examples of which are shown. This characteristic, together with the Quaternary age of the rocks, confirms that the extensional fractures were active features in the northern part of the Danakil Depression. Approximately 10 such open fractures, which have clear asperities, were measured and all found to be consistent with an overall ENE-WSW (59.4°) extension direction of the open fractures orthogonal to the mean trend of the axial structures (*i.e.*, 333°) (Fig. 5).

3. The Danakil Depression and the Dallol Geothermal Area

The Danakil Depression is a narrow, arid lowland plain (~ 250 km long) mostly lying ~ 100 m below sea level (b.s.l.) but reaching as much as 124 m b.s.l. in Lake Assale (also spelled Lake Asale or Asshale and less frequently known by its official name Lake Karum), Lake Bakili, and near the Dallol volcano (Fig. 4), and therefore represents one of the lowest land areas in Africa and in the world (Table 1) including one of the lowest-elevation subaerial volcano-hydrothermal systems on Earth. It runs inland, approximately NNW to SSE, quasi-parallel to the coast of the Red Sea (funneling out to the south: ~ 15 km wide at the north and widening up to 70 km to the south) from which it is separated by tectonic barriers. The Danakil Depression can be divided in two physiographic domains represented to the north by the Dallol area and to the south by the Erta'Ale volcanic range (Fig. 4). Axial shield volcanoes rising from 0.3 to 1 km typify the southern part of the Danakil Depression, whereas its northern part is dominated by a largely deserted, 4000 km^2 salt plain known as the Dallol or Assale plain, hosting the Dallol volcano.

The western border of the Danakil Depression is bounded by the Ethiopian Escarpment or Highland (the highest peaks standing well above 3500 m above sea level [a.s.l.]), which includes prominent marginal grabens, such as the Maglala-

Renda and Dergaha-Sheket grabens, the fill deposits of which accommodate a drop in elevation of up to ~ 3000 m to the ridgeline of the escarpment and less than ~ 1000 m to the marginal areas up to 100–150 m b.s.l. at the floor of the Danakil Depression. The western border has a more distinct rift architecture and morphology than the eastern border, which comprises the Danakil Alps (average height of 400 m a.s.l.; highest peak at the Nabro stratovolcano, 2218 m a.s.l.), a narrow (~ 500 km long) NW-SE trending volcanic ridge (*e.g.*, Tesfaye *et al.*, 2003; Beyene and Abdelsalam, 2005). To the north, the low volcano-tectonic barriers (including the Jalua and Alid stratovolcanoes, 713 and 904 m a.s.l., respectively) south of the Gulf of Zula and the city of Mersa Fatma protect the Danakil and Afar Depression from marine flooding; and to the south, the Danakil Depression hosts the ~ 100 km long, axial volcanic Erta'Ale Range (NNW-SSE trending), where the Ale Bagu stratovolcano rises up to 1031 m a.s.l. and Erta'Ale ("smoking mountain" in the Afar language) features a spectacular permanent lava lake (*e.g.*, Barberi and Varet, 1971).

The age of the Dallol dome is postdated by the age of the thick evaporite deposit of the Assale salt plain (see Section 3.1), whereas the hydrothermalism of the area (Dallol Hot Springs, Black Pool and Gaet'ale Lake) was possibly generated by a phreatic explosion in 1926 (*e.g.*, Holwerda and Hutchinson, 1968; Siebert *et al.*, 2010); since then, explosive volcanic episodes, perpetual and ephemeral hydrothermal venting, small geysers and pools, and several seismic events have been reported in the area (*e.g.*, Ogubazghi *et al.*, 2004; Chernet, 2011; Craig *et al.*, 2011; Nobile *et al.*, 2012; personal communication with Afar guides).

The ellipsoidal Dallol dome (ENE-WSW long axis) features an approximately 1 km main crater atop a wide dome of approximately 5 km E-W diameter, located *ca.* 80 km NNW from the axially aligned active volcanoes of the Erta'Ale Range. It consists of bedded anhydrite and halite with an elevation of about 45–50 m above the Assale salt plain (here 124 m b.s.l.) (Fig. 6). Hydrothermal activity is fueled by water heated and enriched in gases by a shallow magma reservoir that lies primarily beneath the volcano (*e.g.*, Schofield *et al.*, 2014). Field observations permit the recognition of at least three main sites within the Dallol

TABLE 1. LIST OF THE LOWEST POINT ON LAND ELEVATION (B.S.L.) OF GEOLOGICAL DEPRESSION (COMPILED FROM MANY SOURCES AND UPDATED FROM GOOGLE EARTH)

Location	Country	Elevation b.s.l.	Latitude/Longitude ^a
Dead Sea Depression	Israel, Jordan	~ 415 m	$32^\circ 32' 15''\text{N}$ $35^\circ 30' 20''\text{E}$

^aApproximate.

FIG. 6. Panoramic views of the Assale salt plain (see also Fig. 4). Photographs show the regular polygonal patterns (A) and their breakage forming tepee desiccation features (B) on the (halite) salt plain. The average diameter of an individual desiccation cell is approximately 60 cm, but polygons can easily reach 3 m diameter with 20–40 cm high tepee rims.

hydrothermal system, each with distinct vent characteristics: the Dallol Hot Springs, the Gaet'ale Lake, and the Black Pool (Fig. 7).

The Dallol Hot Springs is a hydrothermal field less than 1 km² in diameter featuring disseminated ephemeral and inactive fumaroles and geyser cones steaming and spitting hot and warm brines, forming mounds and yellow-green pools that are mostly concentrated in the Dallol volcanic crater (Fig. 7). It is likely that seasonal variations, magmatic and seismic events, and anthropogenic intervention are among the many factors affecting the equilibrium of the hydrothermal system. Since 2013, it has been possible to document newly forming crevices, fumaroles, small vents, and steaming pools

(with a SSE trend distribution) along the south flank of the crater and at its base on the nearby salt plain. The Dallol dome still hosts the rusting ghost of the mining camp (14°14'16.19"N, 40°17'44.93"E) of the Ralph M. Parsons Company, USA, which conducted exploration in this area from 1958 to 1968.

Gaet'ale Lake (14°12'48.50"N, 40°19'16.50"E) (Master, 2016), also called by the Afars Geda Lé (which means "spring water" in the Afar language) and also informally known as the Yellow, Boiling, Geyser, Killer, and Acidic Lake (Warren, 2016, and other informal sources), is a hydrothermal pool located less than 4 km SE of the Dallol volcanic crater. The perpetually bubbling waters of Gaet'ale

FIG. 7. Satellite overview of the Dallol area and its hydrothermal sites. The hydrothermalism related to the Dallol volcanism includes (1) the active and inactive Dallol Hot Springs mostly concentrated in the Dallol crater, (2) the active and inactive Gaet'ale Pool and related satellite pools and pits that can be observed along the (NW-SE) fracture alignment (dashed line), and (3) the "bischofite" field including the Black Pool in the area of the so-called Black Mountain. DK-10-04B: drill hole, Allana Potash Corporation (2012). Source data: Landsat 8 pan-sharpened RGB-321 color composite acquired on October 6, 2016. Image courtesy of the U.S. Geological Survey (scene ID: LC81680502016280LGN01).

Lake have average pH and temperature values of 3 and 55°C, respectively. Gaet'ale Lake is the largest (less than 50 m in diameter) of a number of small active and relict pools aligned along a NW-SE tectonic trend running parallel to the shallow dike intrusion feeding the geothermal activity of the Dallol volcano on its western flank (Nobile *et al.*, 2012). According to Master (2016), the Gaet'ale water spring formed after the 2004–2005 seismic events as a small 3 m high geyser that became in the following 5 years a muddy-briny pool of water. Since the first survey of Gaet'ale Lake in 2013, new small pits (from less than a meter up to a few meters) have opened along the NW-SE tectonic lineament intersecting the southeast of the Dallol crater, some of them enlarged due to dissolution effects while others are presently ephemeral and relict forms (Fig. 7).

The Black Pool is a small, hydrous magnesium chloride-rich pool of slightly boiling acid (14°13'12"N, 50°17'15"E; 122 m b.s.l.; T_{average} 56°C and pH 1.4 were recorded in January 2018) located less than 2.5 km SW of the Dallol crater, on the north side of the ca. 2 m high dark mound informally named Black Mountain and associated with potash ore deposits and surrounded by a large bishofite deposit and an active fumarole field (Holwerda and Hutchinson, 1968; Warren, 2016; field observation). Bishofite outflow events were reported in 2011–2012, and the size of this geothermal area was estimated at 0.3 km³ in 2015 (Franzson *et al.*, 2015).

Until only several years ago, the Dallol area was considered one of the most remote places on Earth. Only at the end of 2015 did dirt and gravel roads from Hamed'ela (also reported as Ahmed'ela, Ahmed'ila, Amed Hela, or Ahmedela) reach the now-permanent Afar village, from where it is possible to access the Danakil salt plain, the Dallol hydrothermal area, and the nearby Canadian Allana Potash Corporation mining camp—engaged in the development of potash assets in Ethiopia (Allana Potash Corporation, 2012)—to Berhale (about 75 km away) and to Mekelle (about 200 km

to the SW), the largest city in northern Ethiopia. Recent developments in the region have rapidly changed, and will continue to improve, the lives of the nomadic Afars and miners. Here, Afars are still mining salt rocks and transporting the production from the Danakil salt plain to Berhale by camel and donkey caravans (Fig. 1B).

3.1. Dallol geothermal area: stratigraphic and minero-petrographic features

Stratigraphic data for the northern Danakil area are scarce in the literature, and the definition of the main stratigraphic units is mostly unclear. At very local scales, however, a different stratigraphic nomenclature and subdivisions for the formations and rock units have been proposed (Table 2; Fig. 8) (for reviews see Ralph M. Parsons Company, 1966; Holwerda and Hutchinson, 1968; Bannert *et al.*, 1970; Brinkmann and Kürsten, 1970; Hutchinson and Engels, 1970; Lalou *et al.*, 1970; Bonatti *et al.*, 1971; Garland, 1980; PEC Engineering Division Mine, 1984, 1986; Smewing and McKeon, 1989; Carniel *et al.*, 2010; Allana Potash Corporation, 2011, 2012; Abbate *et al.*, 2015; Warren, 2016; Varet, 2018).

Based on the stratigraphic units already recognized in the literature (Table 2; Fig. 8), we propose for the Dallol area a stratigraphic reconstruction based on our field observation (see also Fig. 4). Nonetheless, more field observations and detailed studies are required in order to obtain a well-defined stratigraphy for the northern Danakil Depression.

The northern part of the Danakil Depression—the location of the Dallol area—is a conical, tectonic depositional basin that opened southward from the Gulf of Zula to the central Afar region as part of the subaerial segment of the crustal spreading rift process that began in the early Miocene Epoch (Figs. 1–4). The rifted Precambrian granitic and metamorphic basement complex does not outcrop within the northern Danakil Depression but is exposed in the Ethiopian

TABLE 2. SCHEMATIC STRATIGRAPHY RECONSTRUCTION OF THE DANAKIL DEPRESSION AND DALLOL GEOTHERMAL AREA COMPILED FROM DIFFERENT SOURCES (SEE REFERENCES IN THE TEXT)

Age	Formation/Units	Description	Volcanics
Pliocene-Holocene	Assale salt plain	Halite, gypsum, potash salts, clays, and shale deposits	Intercalated with the Aden Volcanics units
	Afdera Formation	Lacustrine and fluvial sediments (marls, gravels, limestone, and diatomites). In the Dallol area the Afdera Formation is almost missing, and the Enkafala Formation transitionally passes to the Assale salt plain.	
	Enkafala Formation ^a (also reported as White Series and partially overlapping with the Zariga Formation)	Gypsiferous deposits, bedded halite, anhydrite, potash salts indicating a marine transgression	
Miocene	Danakil Formation ^a (also reported as Red Series and equivalent of the Dogali Formation)	Conglomerates and sands with locally gypsiferous madstones and limestones intercalated with basalt flows intrusion unconformably overlain by the Enkafala Formation	Intercalated with basalt lava flows and intrusions, and ashes of the Afar Basalts

^aThe Evaporite Sequence (Holwerda and Hutchinson, 1968) described for the northern portion of the Danakil Depression—specifically about 10 km west of Dallol volcano, in the so-called Musley area—may partially correspond to the marine sediments of the top part of Danakil Formation and to the Enkafala Formation (see also Fig. 8).

FIG. 8. Simplified stratigraphic column of the Allana DK-10-04B drill hole (−124.33 m of elevation b.s.l.), which is located less than 4 km south of the Dallol volcano (see Fig. 7). Here the Evaporite Sequence (Holwerda and Hutchinson, 1968; Warren, 2016) is represented from bottom to top by the (1) Lower Salt Rock Formation consisting of halite with coarse anhydrite and clay layers, the (2) Houston Formation consisting of anhydrite with clay layers rich in potash minerals—kainite, halite, carnallite, sylvite—and the (3) Upper Rock Salt Formation consisting of halite with gypsum and anhydrite interbedded with clays. The detrital deposits (alluvial gravels, sandstones, detrital gypsum, and halite) of the Evaporite Sequence are not present in this area. The Houston Formation (from bottom to top) contains the most interesting potash-bearing intervals: Kainite, Intermediate and Sylvite Members, and the Marker Beds. Modified from Allana Potash Corporation (2012).

highlands adjacent to the Danakil Depression and in the Danakil Alps.

The northern Danakil Depression is dominated at the surface by wide evaporite deposits (Assale salt plain) above which, to the south, NNW-SSE (rift axis) Quaternary-Recent volcanic edifices (basalts) gently rise from 0.3 to 1 km (Fig. 4). The evaporitic deposits interfingering continental (fluvial and lacustrine sediments) and shallow marine deposits are set on multiple events of fissure-fed basaltic lava flows. At the base of the steep escarpments, flat layers of sand-to-silt-sized alluvial deposits overlain by alluvial fan deposits are observed on the depression floor.

The massive, marine evaporite deposits (along the axis) of the Danakil Depression formed when the region was connected at the north to the Red Sea (about 200,000 years ago), which remained isolated during the Pleistocene (Holwerda and Hutchinson, 1968; Tazieff *et al.*, 1969; see Varet, 2018, for review). Periodic freshwater flooding from the surrounding highlands has been and still is responsible for the formation of recent salt deposits (Assale salt plain). Danakil evaporite deposits have been targeted by several exploration programs since the early 1900s when the pre-

liminary survey was conducted by Italian explorers Adriano and Tullio Pastori and the CMC (Compagnia Mineraria Coloniale), an Italian mining company that first discovered the potash (K-rich minerals) ore deposit in the Dallol area and revealed its potential (for a review of Danakil potash exploration, see Lupi, 2009). According to the (public) data collection from the drill core (*ca.* 1000 m drill cores) and geophysical field surveys presently available from all the potash exploration programs, the deepest part of the Danakil Depression is filled with at least 2 km thick sediments that comprise the Danakil, Enkafala, and Afdera Formations (Mitchell *et al.*, 1992; Redfield *et al.*, 2003; Allana Potash Corporation, 2011; Darrah *et al.*, 2013; Warren, 2016).

The shallow magma intrusions buried by the evaporitic deposits at the Dallol area (Nobile *et al.*, 2012) control the dome-shaped uplifted deposits that in turn result in strongly altered and now partially eroded halite and potash beds. Moreover, magma intrusions are the engine of the Dallol geothermal field (Holwerda and Hutchinson, 1968; Nobile *et al.*, 2012; Darrah *et al.*, 2013). In the Dallol volcanic area beneath the crust of modern salt (halite) dissolved and re-precipitated by episodic floods from Assale Lake (*e.g.*, Martini, 1969), the stratigraphic sequence consists of interbeds of evaporite mineral phases including halite, gypsum, anhydrite, kieserite, and shale with a potash succession including mostly carnallite, kainite, and bischofite at places showing fluid and gas inclusion (such as CH₄, H₂O, CO₂, H₂O_{vap}) (Table 3). A marine brine source of the kainite and carnallite units at more than 800 m depth in the salt flat in the Dallol volcano area could explain the high levels of Mg and SO₄ (Holwerda and Hutchinson, 1968; Warren, 2016).

3.2. Dallol geothermal area: the hot springs

Many typical terrestrial hydrothermal features characterize the Dallol hot springs: hot acidic waters, active and inactive fields of single- to multi-vented spring mounds or cones, small geysers, fumaroles, circular to subcircular shallow ponds and/or pools forming characteristic terraced surfaces filled by hot brines, together with salts and sulfur/sulfide deposits emanating intense S- and Cl-rich vapors and (recrystallized) iron-oxide crusts mixed with fine, older clay sediments in the form of muddy evaporites. In the following, we outline the major characteristics and morphological features of the Dallol geothermal area.

3.2.1. Water geochemistry. Thermal waters emerging from the Dallol area consist of hot (up to *ca.* 112°C ± 0.1°C; *in situ* temperature measurement performed using a portable VWR digital thermometer with a precision of ±0.1°C), hyperacidic, Na-Cl brines with exceptional chemical-physical characteristics entirely lacking in carbonate species and with high chloride content, which can be summarized as follows: (i) the lowest measured pH value is 0 (pH measurement performed using a multiparameter WTW Model 340i with an accuracy of ±0.1 coupled with test strips capable of determining pH ranges with as high an accuracy as possible, as an instrument of control); (ii) high TDS (total dissolved salts) content up to 366 g/L; and (iii) extremely high concentrations of Fe and Al have been recorded up to 22,000 and 1,100 ppm, respectively (Table 4). As suggested by

TABLE 3. LIST OF DIFFERENT MINERAL PHASES AT THE DALLOL AREA COMPILED FROM FIELD AND LABORATORY OBSERVATIONS (ITALICS) AND FROM LITERATURE (HUTCHINSON AND ENGELS, 1970; ALLANA POTASH CORPORATION, 2011, 2012; WARREN, 2016, AND REFERENCES THEREIN)

^bChlorine minerals commonly contain liquid, gas, or solid inclusions composed of CO₂ and hydrocarbons.

Note: no sulfides were detected.

classification diagrams such as the square classification diagram of Langelier and Ludwig (1942), these unique thermal waters plot close to typical present-day Mediterranean seawater composition but with a salinity 10 times higher (Fig. 9). Although the salinity is very similar to that of esti-

mates of the Dead Sea in 2002, the relationships between the fundamental ions are very different (Capaccioni *et al.*, 2003). For example, contents of Na⁺ appear slightly lower with respect to those expected from a conservative evaporation of marine Cl⁻, probably due to the precipitation of NaCl (Fig. 9B). Mg²⁺ is also generally lower, whereas SO₄²⁻ concentration is apparently less influenced by anhydrite precipitation than in the Dead Sea basin. K⁺ appears 3–4 times more concentrated with respect to that expected according to conservative evaporation. Calcium shows similar behavior, although to a lesser degree. Considering Br⁻ as a conservative indicator, instead of Cl⁻, ions such as Na⁺, K⁺, Ca²⁺ including Cl⁻, appear largely to exceed the expected values; F⁻ in particular displays concentrations up to 100 times those expected.

The conceptual model describing the origin of these thermal waters must be based on both that the local elevation is 120 m b.s.l. and that the waters are hyperacidic and gas-rich. Elevated salinity should result from the leaching of evaporite salts and/or from evaporation of connate/fossil seawater, coupled with the precipitation of soluble salts, such as NaCl, CaSO₄, and CaF₂. The extremely low measured pH values can only be the result of inputs of very acidic gases, such as HCl, HF, SO₂, and H₂S as testified by the observed excesses of anions. The only possible source of these anions is the dissolution of very acidic gaseous species possibly related to processes of magma degassing at depth. The acidity of the water is then maintained due to the lack of alkaline capacity of the host rocks. The excess of cations is likely related to intense leaching of silicate rocks, although this cannot be confirmed due to a lack of data regarding rock composition at depth. The dissolution of basaltic rocks at depth seems to be a negligible phenomenon since acidity should produce a significant increase in Mg²⁺, which is not observed.

3.2.2. Mounds, geysers, pools, and terraces. The Dallol crater is characterized by localized hydrothermal activity with intermittent small geysers, salt spring mounds, and cones (Fig. 10) emanating extremely acidic (pH ~0–0.2 or below 0; Franzson *et al.*, 2015, reported pH values of –0.74 [winter 2012] for these acidic waters), hypersaline, hot (up to 112°C) hydrothermal waters that form pools, and terrace and microterrecette morphologies (Fig. 10C).

TABLE 4. GEOCHEMICAL COMPOSITION OF THE GEOTHERMAL WATERS COLLECTED IN OCTOBER 2013 FROM THE DALLOL HOT SPRING SITE (SEE FIG. 7). WATER SOURCE SAMPLES WERE COLLECTED FROM SITES D1 (14°14'16.69"N, 40°17'52.08"E) AND D2 (14°14'21.07"N, 40°17'56.08"E) (SEE FIG. 11)

Sample	T°C	pH	Na ⁺	K ⁺	Ca ²⁺	Mg ²⁺	HCO ₃ ²⁻	CO ₃ ²⁻	F ⁻	Cl ⁻	NO ₂ ⁻	Br ⁻	PO ₄ ²⁻	SO ₄ ²⁻	TDS g/L	Si _a	Si _h	Si _f

All concentrations are in ppm.

FIG. 9. (A) Chemical classification of the Dalol Hot Springs thermal waters (classification diagram after Langelier and Ludwig, 1942). (B) Na^+ - Cl^- diagram from waters of Dalol Hot Springs and the Dead Sea. Dalol spring waters show a marine influence with Cl^- excess related to strong acidic gas input.

The Dallol Hot Springs' center frequently changes its position (Fig. 11), as evidenced by field monitoring (from 2013 to 2018), including significant water table fluctuation, and confirmed by a field of relict hydrothermal structures such as inactive (relict) mounds, fossil terraces, dried pool,

and mushroom-like structures (see below). The fluctuation of the geothermal water level and ephemeral position of the spring sources must be connected to the combination of evaporative and groundwater processes and magmatic activities.

FIG. 10. Dallol Hot Springs site (see Fig. 7). (A) Panoramic view of a field of chimneys, cones, and spring mounds, and sulfur and halite deposits. (B) Circular to subcircular halite mound (~ 1 m high). Note the red-brownish color on the ground and on the mound walls, reflecting oxidation of Fe in the dry mounds geyser ponds. (C) An erupting halite geyser (arrow, ~ 40 cm high). Note that the microterraces originate from the slope of the mound. (D) Halite (white) crystal formation on briny water surface. Note the thin salt veils floating on the water surface (arrow). (E) Sulfur and halite-sulfur deposits. Note the oxidation of Fe when exposed to the air (arrow).

Salt mounds and cones range in size from several tens of centimeters to 3 m in height and have near-circular shapes that can reach several meters in diameter at their bases (Figs. 10A–10C, 12). These rarely occur as isolated bodies; mostly they generate a field of mounds or cones reaching about the same height (in the same field).

The Dallol geysers, cones, and hot springs spit water and release steam (H_2O) and gas dominated by hydrogen sulfide (H_2S), sulfur dioxide (SO_4), hydrogen chloride (HCl), and minor carbon dioxide (CO_2). The waters of the Dallol springs have temperatures exceeding 100°C at the vent source (the highest temperature recorded being 112°C),

forming shallow, semicircular to circular ponds and pools of less than 1 m to tens of meters in diameter filled with light yellowish or yellow-greenish brines, which are commonly contaminated with mud. The largest pool ($\sim 1000\text{ m}^2$ wide) with slightly boiling, dark green-brownish water at the Dallol Hot Spring site was observed in October 2013; In this now dry area, it is now possible to observe the sparse fluid and gas escape apertures (vents) from which the hydrothermal waters were rising.

The supersaturated water, especially at the source vent, engenders rapid deposition of white, yellow, and orange salt precipitates that alter to red-brownish colors reflecting the oxidation of Fe (*e.g.*, Figs. 10 and 12). The exposed ground of the dried pools shows features of the inactive hydrothermal fields that could be directly compared with the nearby active analogs such as relict mounds and terrace structures (Figs. 13 and 14).

Terrace morphologies at the Dallol volcano resemble those observed in the Mammoth Hot Springs of Yellowstone National Park and other similar settings. Despite their different chemical compositions—at Yellowstone, terraces are carbonate, whereas at Dallol they consist of halite—they produce closely comparable morphologies. Similarly to Yellowstone, the decimeter- to centimeter-scale terraces at Dallol are bounded by steep-sloped rims that function as dividers between pools at different levels (Figs. 10C and 14). Hot water flows from the top of the vent down to the distal sectors of the spring system exhibit a rapid drop of temperature—ranging from 100 – 112°C at the exit from the hot spring down to 33 – 40°C in the distal pools—that could have a significant influence upon the distribution of the microbial communities potentially hosted by the spring system. The largest of these pool structures measure several square meters at their surfaces.

Where the gradients of the spring system are lower, a dense network of salt rims is the likely product of the combined action of reduced gradients and the salt precipitation favored by the rapid reduction of the water temperature. At the surfaces of the pools, where the temperature falls most rapidly, thin saline films can be formed in only a few minutes and are clearly visible from direct field observation. As a result of continuous water flow at the surface of the pools, these newly formed films tend to migrate and accumulate at their edges, such that they thicken the salt rims and favor the formation of small-scale terrace structures. Salt precipitation probably also induces some rise in the water level of the pools so as to further facilitate terrace formation. Since the precipitation of halite in the spring pools at Dallol is an easily reversible phenomenon (and rapidly changes to dissolution), terraces do not exhibit steady state, explaining the rapid changes that can be observed from one day to the next.

Widely described as small-scale morphologies in geothermal travertines, terraces have a key role as suitable environments for hosting living microorganisms, such as cyanobacteria and eukaryotic algae, and as a repository of fossilized microbial life. These functions, though greatly reduced in extremely harsh environments, may be present in such morphologies at Dallol.

3.2.3. Salt mushroom- and artichoke-like structures. Irregular, subcircular mushroom- and artichoke-like structures (Fig. 15) are among the characteristic salt (halite-

FIG. 11. Satellite view of the Dallol crater showing the location of the ephemeral hydrothermal hot springs (arrows) in 2013 (A) and in 2018 (B). In both panels the hydrothermal systems active in 2013 are indicated with white arrows, whereas black arrows indicate systems active in 2018. Data source: Google Earth (2018 imagery: CNES/Airbus; 2013 imagery: DigitalGlobe, image centered at $14^\circ 14' 25.25''\text{N}$, $40^\circ 17' 57.78''\text{E}$). Note the D1 and D2 are the water sampling sites selected for water geochemistry in 2013 (see also Table 4).

FIG. 12. Characteristic multivented spring mound with several fluid and gas escape features (red arrows) at the Dallol Hot Springs site. Note the base of the large mound dominated by microterraces (green arrows). Here the color ranges from white to yellow and red-orange to dark brown. Note the H_2S - SO_4 - H_2O -dominated gaseous emission (black arrow). Field of view ~ 3.7 m.

dominated) morphologies of Dallol, where they emerge from dry shallow pools between the south and the central area of the volcano. With diameters that can reach (and exceed) 1.5 m, these salt mushrooms abound in the bottoms of shallow pools, occurring both as single and composite structures. Mushroom caps have irregular forms with raised edges and depressed central areas that presumably depend upon their stage of growth. Closer inspection of their upper surfaces shows concentric rings likely produced during growth. Significantly smaller than the mushroom-like structures, the artichoke-like structures have typical sizes of about 10–15 cm and may represent the early stages of development of the mushrooms. Robust fringes, presumably produced during their development, crown the artichoke-like structures.

Salt morphologies similar to mushrooms and artichokes have been described from other hypersaline settings, such as near the shoreline of the Dead Sea (Talbot *et al.*, 1996). Large salt (gypsum and halite) mushrooms have also originated in shallow saline lakes (*salares*) of the Atacama region, where the selenite crystals composing their internal structure trap an abundance of bacterial cells and organic matter (Barbieri *et al.*, 2009).

3.2.4. Salt rims. A number of open fissures or small gas pipes or escape structures with single or coalescent circular sections (average diameter: 7–8 cm) have been observed on the salt substrate of the Dallol caldera (Fig. 16). Thin (a few

millimeters thick), fragile white salt rims forming small dome structures can be observed growing around these fissure openings. The white salt rims are composed of pure sodium chloride in the form of halite. These structures develop high cylindrical or semicylindrical tubes of several centimeters in height. Most of them are well preserved, although some display an opening produced by their broken upper surface (Fig. 16C). These halite salt rims form during vapor emission from active small-sized vents and the concomitant direct precipitation of salts (*e.g.*, Talbot, 2008).

Salt rim structures similar to those described herein, but with a different genesis, have been reported in a few restricted desert areas such as the Cordillera de la Sal in Chile, the Qarhan Salt Lake in China, and the gypsum and anhydrite deposits of the Neuquen Basin in Patagonia, Argentina (*e.g.*, Stoertz and Ericksen, 1974; De Waele and Forti, 2010, and references therein). The salt rims and blisters in Chile are also made of pure halite and develop on the salt crust of the Atacama Desert, and have been interpreted to form during cycles of ephemeral condensation-evaporation processes occurring at small orifices at the interface between the salt surface and the atmosphere. This usually occurs immediately after very short episodes of rain.

3.2.5. Climate and vegetation. The Danakil Depression and, in particular, the Dallol area are characterized by consistently very hot climatic conditions with extremely limited rainfall. These persistently extreme temperatures

FIG. 13. Field of meter-scale relict hydrothermal mounds and cones (**A**, **B**). In (**A**), note the active Dallol Hot Springs center in the background (black arrow).

and low precipitation gradients seem intensified by a combination of factors such as the low latitude of the locality (latitude: 14.14°N), its altitude below sea level (~ 124 m b.s.l.), and the intense geothermalism and active volcanism.

The daily average temperature on the salt plain during winter is consistently above 30°C and above 34–36°C on the Dallol area; in both areas, however, daytime temperatures routinely exceed 40°C. Summer temperatures can easily rise to 50°C and above, especially in the Dallol area (during one field campaign conducted in October 2013, we registered daytime temperatures of 54°C). Average annual rainfall is between less than 50 and 200 mm per year but is highly variable from year to year, always below 400 mm per year. An APCE-FWS-20 weather station (PCE Instruments) has been installed in the Dallol hydrothermal area (14°14'18.15"N, 40°17'53.76"E, 89 m b.s.l.) and its mast located 50 cm from

the ground in order to record environmental parameters such as air pressure, air temperature, humidity, and wind speed near the ground surface. These parameters were monitored in January 2017 during four consecutive days at 10:00 am, 11:00 am, and 12:30 pm. The maximum air temperature recorded was 45°C (at 12:30 pm) with a corresponding humidity of 29% and wind speed of 29 km/h. Humidity is related to temperature and wind speed such that high air temperatures and wind speeds correspond to lower humidity.

The region, having the highest average daily and monthly temperatures in the region, can be considered the end member of the hyperarid desert climate and is classified within the BWh hot desert climate Köppen-Geiger climate zone (see Pedgley, 1967; Warren, 2016). Due to its hot climate and the limited annual rainfall, the Danakil region including the Dallol area, is known as the hottest place

FIG. 14. Panoramic view of active (A) and inactive (B) terrace morphologies at the Dallol Hot Springs site. Meter-scale terraces consisting of halite (A) and/or halite-anhydrite (B) and originating from the slope of hot spring mounds (black arrows). Note the fluid escape features exposed on the ground of the dried pools (white arrows). Scale bars: 40 cm (A) and 20 cm (B).

on Earth, giving rise to deserted and often toxic (highly acidic and H_2S -, SO_4 -, and CO_2 -rich) environments with largely undocumented, rare endemic fauna and flora and sparse nomadic villages. Nonetheless, in the last decade, exploration and mining activities, together with the need for labor and the increasing presence of tourists, have resulted in the Hamed'Elä village (approximately 10 km southwest of the Dallol caldera), previously occupied only during the cold season, becoming permanently populated.

4. Dallol Geothermal Field in an Astrobiological Perspective

Terrestrial hydrothermal springs have long been considered among the most important environmental analogs in the search for life traces on early Earth and Mars (*e.g.*, Walter and Des Marais, 1993). Their importance includes geological and geomorphological structures, mineral precipitation and alteration features that may ultimately lead to biosignature preservation (Schulze-Makuch *et al.*, 2007; Allen and Oehler, 2008; Pondrelli *et al.*, 2015; Ruff and Farmer, 2016; Barbieri and Cavalazzi, 2018). The exploration of terrestrial analogs can

provide insights into the possible presence and nature of spring deposits on Mars, as well as help develop techniques for identifying them from remote sensing data and thereby define the future of astrobiological research.

Despite the high-resolution imaging and data presently available from other planetary bodies and that we expect to obtain from future exploration missions, the understanding of structures, processes, models, and habitats from Earth is still the most reliable means of interpreting planetary environments, especially in the case of other rocky planets. In the case of Mars, in particular, the convergence between what we know of the geological history of the planet and our growing understanding of the physical-environmental features of Dallol deserves a precise assessment. Current evidence suggests that martian hydrothermalism, which has been recognized in several regions of the planet, is either related to subaerial processes type and associated with phenomena of volcanism (volcanic edifices, basaltic deposits in the vicinity, etc.) or caused by impact cratering processes. Considering also the presence of evaporites, we find an environmental setting that is extraordinarily similar to the present situation in the Dallol volcano.

FIG. 15. (A–B) Active mushroom-like structures (field of view *ca.* 4 m) and related relict morphologies (field of view *ca.* 5 m), respectively. (C) Field of relict artichoke-like structures. The black arrow in (C) is detailed in (D). In (D) the marker for scale measures 13.5 cm.

Therefore, the direct study of hydrothermal systems such as the extreme acidic and hypersaline Dallol Hot Springs center can have strategic importance for astrobiology since it allows the investigation of surface hydrothermal systems with similarity to those strongly suspected on Mars.

4.1. Relevance of hydrothermal systems in astrobiology

Hydrothermal systems are considered among the earliest habitable environments (Nisbet and Fowler, 1996; Arndt and Nisbet, 2012); indeed, hydrothermal systems associated with either submarine volcanic activity or terrestrial (subaerial) hot springs may have functioned as the environment in which life arose and, therefore, hosted the first living communities (Arndt and Nisbet, 2012; Grosch and Hazen, 2015; Djokic *et al.*, 2017). This is supported by evidence from a number of scientific domains. The plurality of chemistries and hydrodynamic conditions near hydrothermal systems can create a range of gradients in, for example, temperature, pH, salinity, redox conditions, elemental fluxes, and fluid dynamics (Russell *et al.*, 2010, 2014), thus forming a range of microcosmic to macrocosmic disequilibrium systems. When

life originated on Earth (more than 3.5 billion years ago), the environmental conditions at both planetary and local scale were profoundly different from those of the present (Cavalazzi *et al.*, 2018) and suggest that the earliest life inhabited extremophilic niches that were exclusively anaerobic, (hyper)thermophilic, and metal-saturated (Frausto da Silva and Williams, 2001; Saito *et al.*, 2003; Gaucher *et al.*, 2010). Enzymatic and phylogenetic approaches consistently estimate that early life would have inhabited a thermophilic setting (Nisbet and Fowler, 1996; Gaucher *et al.*, 2010) which, when viewed through the spectrum of ocean chemistries expected for the early, anaerobic Earth, suggests further that the environment was necessarily rich in metal cations (Frausto da Silva and Williams, 2001), hence the suggestion of hydrothermal systems.

The diversity of habitats present in the Dallol hydrothermal springs, together with the requirements in terms of mechanisms and biochemical demands of life to adapt to this most extreme environment, allow this unique place to serve as a natural laboratory to explore environments for early life, and possible environments in which extraterrestrial life may exist. The Dallol hydrothermal field encompasses a unique geological and active geodynamic setting involving

FIG. 16. White halite salt rims (few mm in thickness) growing around cylindrical openings (small vents, gas escape structures) on the salt bedrock (**A–B**) and dried pool floors (**C**), locally forming bubbles, forms as a result of vapor emission and salt precipitation. Note the orange-yellowish fine crystals growing around the base of most of the salt rims and the globular deposits around the base of the small halite conduits. (A) Marker for scale: 13.5 cm. (B) Scale bar: 10 cm.

the breakup of a continent, incipient ocean formation and volcanism, and thus the coexistence of many natural physical extremes for life (*e.g.*, temperature, pH, salinity, metal concentration). These characteristics, the defining parameters of a locality that is detectable from space, make sites such as

this a potential target for a geologically interesting landing site of astrobiological relevance.

4.2. Extremophiles of geothermal systems

The first thermophilic microorganisms were discovered over 50 years ago in the hot springs of Yellowstone National Park (Brock, 1967). Since then, abundant microbial activity and a number of thermophiles and hyperthermophiles have been described and identified from a variety of geothermal environments (*e.g.*, Vieille and Zeikus, 2001; Amils *et al.*, 2007b; Barbieri *et al.*, 2014). The best-known and most closely studied geothermal fields are in North and South America (*e.g.*, Yellowstone National Park, USA; El Tatio geothermal field, Chile; Laguna Pastos Grandes, Bolivia), Iceland (*e.g.*, Geysir and Krisuvik hot springs), New Zealand (*e.g.*, Taupo Volcanic Zone), Japan (*e.g.*, Nakabusa, Nagano Prefecture), Italy (*e.g.*, Solfatara fumarole), and Russia (*e.g.*, Kamchatka geothermal field).

Although studies have elucidated how extremophiles manage gene, protein, membrane, and nucleic acid structures (*e.g.*, extremolytes) in extreme or stressed conditions (*e.g.*, Vieille and Zeikus, 2001; Babu *et al.*, 2015), there is not as yet a comprehensive understanding of the principles of survival and adaptation, such as thermostability or homeostasis, that extremophiles use in order to conserve their ecologies.

Geothermal regions including active marine hydrothermal vents and subaerial volcanic environments (*e.g.*, hot springs, geysers and exhalations of hot vapors and gas, solfataric fields) pose more than one environmental extreme yet are colonized by metabolically diverse microorganisms. The microbial communities within the marine and subaerial environments are distinctly different due to the different physical and chemical parameters of their settings. Specific archaeal and bacterial groups show strong biases in environmental preferences, particularly based on sulfur cycle chemistry and pH (Teske, 2009). Hydrothermal waters usually show high concentrations of many elements (*e.g.*, Na, K, Fe, Cu, Au) and can be highly supersaturated with respect to a variety of minerals and mineral deposits that may originate in these environments (*e.g.*, Simmons *et al.*, 2005).

Subaerial hydrothermal systems are the product of subsurface geological processes, which result in reduced chemical species including sulfur and iron that become acidic due to proton-releasing oxidation reactions. The microbial diversity of hydrothermal soils (*e.g.*, hot springs) is diverse and includes chemolithoautotrophic (obtaining energy from the microbial oxidation of inorganic compounds), thermophilic microorganisms that can also survive at low pH (acidophilic), such as the sulfur-oxidizing archaea (including genera *Acidianus*, *Desulfurolobus*, *Metallosphaera*, *Solfobolus*, *Picrophilus*, and *Desulfurococcus*) (Schleper *et al.*, 1995; Kurosawa *et al.*, 1998; Simmons and Norris, 2002; Dinarieva *et al.*, 2010). For example, *Picrophilus oshimae* and *Picrophilus torridus* from solfataric sites in northern Japan grow optimally at pH 0.7 (60°C) (Schleper *et al.*, 1995). In contrast, deep-sea hydrothermal systems consist of hydrothermally heated rock materials (*e.g.*, black smokers) in contact with seawater (3–5% salt concentration), which buffers the protons

released by sulfur oxidation reactions, resulting in pH values between 5 and 8.5 (Stetter, 1999).

4.2.1. High-temperature environments and (hyper)thermophiles. Because of their small size, microorganisms have developed special adaptation mechanisms to regulate differences between their internal temperatures and those of the external milieu.

To address the problem of DNA denaturing (*i.e.*, the formation of two single strands), thermophiles depend on protein-DNA interaction and solutes. The thermostability of the DNA double helix is due to DNA interactions with double-stranded DNA-binding proteins similar to histones (Charlier and Droogmans, 2005). The accumulation of organic osmolytes, such as 2,3-diphosphoglycerate also plays a role in stabilizing the secondary structure on the DNA helix (Santos and da Costa, 2001); however, above 90°C, DNA damage still occurs at a 1000-fold higher rate than at 25°C. Hyperthermophiles have, therefore, developed efficient DNA repair mechanisms, which are facilitated by having numerous copies of their genome. For example, experimental works with the hyperthermophilic *Pyrococcus furiosus* have demonstrated that the enzyme reverse gyrase counteracts the effect of DNA melting (Heine and Chandra, 2009).

Thermophiles have also evolved thermostable proteins, which have increased numbers of large hydrophobic residues, disulfide bonds, and ionic interactions that make them less liable to denature when exposed to high temperatures. Chaperone proteins, which are produced during heat shock, also play important roles in enhancing the thermostability of proteins (Schlee *et al.*, 2001). High temperature also affects membrane fluidity, which is essential for cell structure and cellular processes. The mechanism of maintaining cell wall integrity differs between bacteria and archaea; however, both depend upon maintaining a liquid crystal state at high temperatures. For example, the bilayer, in hyperthermophilic archaea, is crosslinked with C40 transmembrane phytanyl chains (Comita *et al.*, 1984).

4.2.2. Acidic environments and acidophiles. Acidophilic microorganisms grow optimally at low pH (< 3). To grow in such conditions, the microorganisms must maintain a pH gradient across the cellular membrane while still producing ATP (adenosine triphosphate), which is important for transporting energy within the cell (for review, see Baker-Austin and Dopson, 2007). A variety of pH-homeostatic mechanisms are employed to restrict protons entering the cells via the cytoplasmic membrane and purging protons and mitigating their effect in the cytoplasm. To help maintain a pH gradient across the cell membrane, acidophiles have a highly impermeable membrane and positive delta Ψ (opposite to neutrophiles), which inhibits the influx of protons using a chemiosmotic barrier (Suzuki *et al.*, 1999). Protons are also removed from the cytoplasm by a proton translocation system that removes protons to access (Michels and Bakker, 1985). If protons penetrate the cell membrane, a range of intracellular mechanisms are employed to limit biological damage. This includes a range of cytoplasmic buffering molecules including basic amino acids that are able to maintain homeostasis by buffering (Castanie-Cornet *et al.*, 1999). DNA and protein damage associated with

acidic conditions can be repaired using chaperone proteins (Jerez *et al.*, 1988).

Most acidophiles obtain energy from reduced mineral compounds; however, at the Río Tinto planetary analog site, some are reported to obtain energy from sunlight (Amils *et al.*, 2007a). In nature, acidophiles have commonly been observed to oxidize elemental sulfur in hydrothermal vents and to oxidize sulfidic minerals in metallic sulfidic mines in order to obtain energy. It is interesting that many acidophiles will cause and/or contribute to acidity of their habitat through, for example, oxidizing sulfur and producing sulfuric acid as a by-product. Low microbial diversity systems oxidizing reduced sulfur have been observed in the Laguna Caliente ultra-acidic volcanic lake (Hynek *et al.*, 2018).

4.2.3. Salt environments and halophiles. Halophilic microorganisms grow in high salt concentrations from 10% salinity to saturation levels and can even survive within salt crystals. Halophilic archaea have been isolated from salt crystals and evaporite deposits in the rock record (*e.g.*, Vreeland *et al.*, 2000, 2007; Schubert *et al.*, 2010; Fendrihan *et al.*, 2012; Stivaletta *et al.*, 2012). Experiments have demonstrated that halophilic microorganisms entombed in halite are able survive detrimental exposure effects associated with the surface of Mars (UV radiation, cold temperatures, and desiccation) and specific terrestrial conditions (*e.g.*, Fendrihan *et al.*, 2009; Mancinelli, 2015). On Earth, halophiles have been isolated from a wide range of environments, among which are salt marshes, undersea salt domes, and subterranean halite deposits from evaporated ancient seas.

To cope with the osmotic stress associated with high salt concentration, microbes have developed two general methods, the salt-in and the salt-out approaches (Oren, 2006). The salt-in approach involves a high concentration of ions accumulating within the cells, for example K^+ , which generates an osmotic equilibrium with the outside environment (Vreeland, 1987). For this to occur, the proteins within the cells need to adapt to survive the high salt concentration; for example, these proteins require a higher number of ionic bridges. In contrast, the salt-out strategy involves the cells actively pumping salt out of the cell to prevent cell damage. To prevent an osmotic pressure developing across the membrane, the cell produces compatible solutes, such as amino acids and sugars (Kempf and Bremer, 1998).

4.2.4. Polyextremophiles. Previous investigations have isolated thermo-acidophilic microorganisms from solfataric fields, which are acidic, high-temperature, sulfate-rich environments (*e.g.*, Segerer *et al.*, 1998; Hedlund *et al.*, 2015; Johnson and Aguilera, 2016). A comparison of genomes from the thermo-acidophilic genera *Picrophilus*, *Thermoplasma*, and *Sulfolobus* has demonstrated a number of features that may contribute to the survival of microorganisms in high-temperature acidic conditions, for example novel enzymes (*e.g.*, Johnson and Aguilera, 2016). Although halophilic alkali-thermophiles have been isolated and their physiology characterized (Mesbah and Wiegel, 2012), there has been little previous work focusing on the adaptation of microbial communities to the combined effects of high

temperature, high salt, and acidic stresses. The Dallol Hot Springs present a unique opportunity to study the microorganisms that grow at high temperature and salinity, and low pH, particularly in discovering novel microorganisms, metabolisms, and adaptation mechanisms.

4.3. Terrestrial analogs for Mars science

Geomorphological and mineralogical data collected by martian missions (orbiters and landers) allows the reconstruction of conditions that, based on terrestrial evidence, can be traced back to hydrothermal activity and volcanism (*e.g.*, Dohm and Tanaka, 1999; Schulze-Makuch *et al.*, 2007; Squyres *et al.*, 2008; Rodríguez and van Bergen, 2016; Ruff and Farmer, 2016; Michalski *et al.*, 2017). The detection of opaline silica deposits in Meridiani Planum (Glotch and Bandfield, 2006) and Gusev Crater (Squyres *et al.*, 2008; Ruff *et al.*, 2011) has generated a great astrobiological interest. Although silica in hydrothermal systems can often be related to abiotic processes, specific silica morphologies, such as nodules and digitations, may require the influence of organisms to develop (Ruff and Farmer, 2016). A further key role played by hydrothermal silica is related to its unparalleled ability for preserving different types of biosignatures (morphological, geochemical, geobiological), even in very ancient terrestrial settings, which is particularly important considering the apparent abundance of hydrothermal environments (one of the presumable cradles of life) on the early Earth and Mars (*e.g.*, Cavalazzi *et al.*, 2018).

Similarly to hydrothermal sites, other surface environments may imply rock-water interactions and the formation of hydrated minerals, as in the case of hypersaline environments. Although characterized by severely limiting factors, hypersaline environments do not prevent the development of prokaryote diversity (*e.g.*, Ventosa *et al.*, 2015). Especially with regard to Mars where, similarly to Earth, there are widespread sulfate- and other salt-bearing deposits, geological and compositional data suggest an origin from evaporitic environments (*i.e.*, a genesis under aqueous conditions) (*e.g.*, Hynke *et al.*, 2015). Hypersaline systems may thus well be considered a primary hydrological target for studies of martian habitability (Barbieri, 2013).

Among the many kinds of hypersaline settings, the most saline and the most acidic aqueous environments are considered particularly challenging, since they impose the requirement for specific biotic adaptations for withstanding a number of physicochemical stresses. These environments would, therefore, be counted among the most extreme on the planet. In hot and extremely acidic hypersaline brine pools at Dallol, the formation of exhalative salt mounds produced by fluid migration through vertical conduits at the ground-air interface takes place. This is a salt volcano environment in which high-density brines, extreme acidity hot waters and gases combine to form a unique hydrothermal circulation system (Hovland *et al.*, 2006). In the case of martian salts, the interaction between fluids (including groundwater and hot hydrothermal fluids) and igneous rock (basalts) may have had a primary role in their genesis (Bullock and Moore, 2004), and therefore the Dallol salt volcano can be considered a reliable terrestrial analog of martian environments (Cavalazzi *et al.*, 2014).

This gives the site a key role in the search for the limits of biotic tolerance and for the preservation of organic compounds and any other biosignature potentially deliverable to the fossil record. In this regard, the survival of cells over millennia in terrestrial sedimentary rocks would have important implications for the search for life on other planets where structures of sedimentary origin exist (Squyres and Knoll, 2005).

The qualitative and quantitative increase of data coming from Mars has enabled an almost Earth-like approach for studying its geoenvironmental evolution. For example, a direct relationship between spring and salt precipitation has been proposed for explaining their combined recovery (Rossi *et al.*, 2008). For the particularly well-studied case of Arabia Terra, the morphological expression of the putative spring deposits consists of crater bulges, hot spring mounds and salt flats in the craters and plateau, respectively (Franchi *et al.*, 2014; Pondrelli *et al.*, 2015) (Fig. 17). In this region of Mars, fluid expulsion features such as fissure ridges, ponds, and mounds have been documented associated with light-toned layered deposits. Polyhydrated sulfates have been detected both in mounds and salt flats, thus constraining the interpretation of such deposits to evaporites. Such an interpretation is consistent with the presence of a meter-scale polygonal pattern disrupting the layers. The dissolution of these deposits, another characteristic suggestive of evaporitic composition, is suggested by morphologies such as rounded shapes, sinuous margins, and quasi-circular depressions. On the plateau, salt flats are interlayered with cross-bedded duneforms interpreted as eolian deposits. The depicted scenario is a desert environment dominated by eolian processes with episodes of water upwelling and spring deposits laterally associated to salt flats. These morphological and compositional features are comparable to the salt deposits in the Dallol area. One should note, though, that the scale of their martian counterparts is one to two orders of magnitude larger; this is true for several martian landforms. Arabia Terra connects the highlands and the lowlands of Mars with relatively low slopes over a wide area, and it is thought to have been formed by a groundwater-dominated hydrological system (Andrews-Hanna *et al.*, 2007, 2010; Andrews-Hanna and Lewis, 2011; Zabusky *et al.*, 2012). The geodynamic setting is thus not directly comparable to the Dallol area, since no rift system is present in Arabia Terra, nor is active local volcanism clearly documented at the time of the deposition of the sulfate-bearing deposits. Nonetheless, a relation between tectonic fractures acting as preferential fluid pathways, fluid upwelling, and evaporite precipitation appears to be present. The sulfate-bearing deposits rest unconformably on top of a probable basaltic succession. An eventual link between fluid upwelling and hydrothermal processes cannot yet be ruled out, nor demonstrated, based on available data. Although an obvious coeval individual volcanic edifice is missing, basaltic emplacement is recorded extensively in the stratigraphic record of Arabia Terra, and it cannot be excluded that some episodes were partly coeval with the sulfate-bearing deposits. Moreover, impact cratering can also trigger hydrothermal activity (*e.g.*, Abramov and Kring, 2005), with magnitude and length of such activity scaled based on crater size. This could explain the difference in thickness of

FIG. 17. Examples of possible martian analogs from Arabia Terra (Firsoff Crater) within light-toned, sulfate-bearing layered deposits. (A) Field of features interpreted as spring mounds (HiRISE image PSP_003788_1820). (B) Perspective view of the layered deposits in (A) disrupted in a polygonal pattern (arrows) (HiRISE DEM PSP_003788_1820/ESP_020679_1820; no vertical exaggeration). (C) Cross-bedding interpreted to represent eolian duneforms on the basis of scale and lack of association with water-related morphologies (HiRISE image PSP_006623_1800). (D) Possible salt plain. The light-toned deposits are disrupted by polygonal patterns (HiRISE image ESP_013031_1800). Modified from Pondrelli *et al.*, 2015.

the sulfate-bearing layered deposits that in the craters can reach up to thousands of meters whereas on the plateau it has been estimated around just a few tens of meters (Pondrelli *et al.*, 2015).

5. Conclusions

The Danakil Depression is located in the northern Afar Region of Ethiopia near the borders of Eritrea and Djibouti. The famous British explorer Wilfred Thesiger described the place as “a land of death”, which is a perfectly apt description for any outsider entering the region. This description not only applies to humans settled in the locality due to the high average temperatures but also to the very harsh conditions faced by the microbial life inhabiting the ecosystems of the area. The very extreme physicochemical parameters make this site a polyextremophilic environment with the potential to harbor, among others, acidophilic, thermophilic, and/or halophilic microorganisms and met-

abolic networks. The physical and compositional features of the Dallol deposits, their mineralogies, sedimentary and alteration features, and their location in a region of basaltic volcanism of planetary-scale importance, are testament to the novelty of this extreme environment and its ability to host life-forms and to preserve biosignatures. It is therefore also a reliable analog to ancient martian environments and habitats. Deep investigation of the characteristics of this unique geological site will improve our understanding of the limits of life on Earth and inform the search for life on the Red Planet.

Extensive spring deposits associated with salt precipitation have also been noted in the martian terrane of Arabia Terra, where their morphological expression comprises spring deposits and salt flats in craters and on plateau similar to those found in the Dallol area. The geological similarities between the Dallol area and various potential hydrothermal systems on Mars indicate that this unique region presents an excellent planetary field analog for astrobiology.

Recently, the Dallol geothermal area and its unique characteristics have been suggested as a geoheritage site, and a geoconservation strategy has been proposed (Asrat, 2018). We concur that, in light of ongoing and future astrobiological and planetary science programs and missions, this region should be considered a target for space strategy plans in Africa and protected as a planetary terrestrial analog.

Authors' Note

In memory of our colleague Bruno Capaccioni, Professor in Geochemistry and Volcanology at the Università di Bologna, who sadly passed away in 2016.

Acknowledgments

Barbara Cavalazzi acknowledges support by the International Cooperation Program between the Università di Bologna and the University of Mekelle. We are grateful to Franco Pirajno and an anonymous reviewer for taking the time to provide comments and suggestions. B.C. would like to kindly thank Ernesto Abbate (Università di Firenze), Judith Rendón, (Hospital of Mekele), Livia Mercatelli (International Office of the Università di Bologna), Solomon Hishe (University of Mekelle), Birhanu Berhe (Temesgen Pharmacy in Mekelle), Zablon Beyene and Mikael Tamrat (Zab Tours Ethiopia), Sister Laura and the Kidane Mehret Mission in Adwa, the Associazione Amici di Adua Onlus and volunteers Samantha, Marina, Serena, Alberto, Tommaso, and Daniele. Finally, but most importantly, B.C. would like to thank the Afars from Hamed'Ele village, who have always been very welcoming. This is a contribution to the Europlanet 2020 Research Infrastructure programme funded under the European Commission's Horizon 2020 programme (No. 654208).
