We report on room temperature low frequency noise due to magnetic inhomogeneities/domain walls (MI/DWs) in elliptic submicron FeCoB/MgO/FeCoB magnetic tunnel junctions with an area between 0.0245 and 0.0675 μm². In the smaller area junctions we found an unexpected random telegraph noise (RTN1), deeply in the parallel state, possibly due to stray field induced MI/DWs in the hard layer. The second noise source (RTN2) is observed in the antiparallel state for the largest junctions. Strong asymmetry of RTN2 and of related resistance steps with current indicate spin torque acting on the MI/DWs in the soft layer at current densities below 5 × 10⁵ A/cm².

The discovery of large tunneling magnetoresistance (TMR)¹–⁶ has boosted interest in magnetic tunnel junctions (MTJs), which show reduced power consumption, high TMR, and spin torque (ST).⁷ While MTJs with sizes of tens of microns are optimal for magnetic field detectors,⁸ junctions below 100 nm are used for ST magnetic random access memories⁹ or microwave oscillators.¹⁰ Electron transport and low frequency magnetic noise in submicron MTJs of some hundreds of nanometers, where single magnetic inhomogeneities (MI)¹¹ and domain walls (DW) play an important role in magnetization reversal, remain poorly understood.

Previous studies of 1/f (magnetic, nonmagnetic, and electronic) noise and random telegraph noise (RTN) focus on MTJs above-micron size with Al₂O₃ (Refs. 12–14) and MgO (Refs. 8,15–20) barriers. Recent advances in understanding of magnetic 1/f noise are summarized in Refs. 14,18 and 19. Our Letter presents both TMR and low frequency noise at room temperature in CoFeB/MgO/CoFeB MTJs with 0.8 nm thick MgO barriers and areas from 0.117 μm² to 0.0245 μm². MTJs of these sizes reveal two qualitatively different, robust, and reproducible RTN types related with single MI/DWs. The resistance steps and related RTN found in antiparallel (AP) state in the easy (elliptic) axis. To compare the noise level in different junctions, we use Hooge factor (f) from: S(f) = x × V²/(A × f), where A is the area, f is frequency (analyzed between 0.2 and 1kHz), and V the bias. Strong deviations from this dependence are usually caused by RTN.¹² Following arguments rule out RTN explanation in terms of pinholes or “hot spots”: (i) large TMR, (ii) robustness of the MTJs to bias and multiple field scans, and (iii) low values of the Hooge factor in the saturated P state (3.1 × 10⁻¹¹ μm²), close to expected from the empirical summary.²²

Multiple slow field sweeps between the AP and parallel (P) states minimize metastable states and lead, for most of the MTJs, to two types of noise behavior depending on the junction area. Most of the smallest junctions (0.0245 μm²–0.0503 μm²) reveal enhancement of the noise in the P state room temperature exceeding 45% (Fig. 1(a)), we present low frequency (1 Hz–10 kHz) noise measurements for 7 MTJs, which reversibly stood biases between 100 and 400 mV. We measured the power spectrum S(f) (Ref. 15) and TMR along the easy (elliptic) axis. To compare the noise level in different junctions, we use Hooge factor (f) from: S(f) = x × V²/(A × f), where A is the area, f is frequency (analyzed between 0.2 and 1kHz), and V the bias. Strong deviations from this dependence are usually caused by RTN.¹² Following arguments rule out RTN explanation in terms of pinholes or “hot spots”: (i) large TMR, (ii) robustness of the MTJs to bias and multiple field scans, and (iii) low values of the Hooge factor in the saturated P state (3.1 × 10⁻¹¹ μm²), close to expected from the empirical summary.²²

The layer stack was deposited by magnetron sputtering in a Timaris PVD cluster tool from Singulus Technologies. Its structure is Ta₅/Cu-N/90/Ta₅/Pt-Mn20/Co-Fe 2.2/Ru0.8/Co-Fe-B2/Mg0.8 +1200 s oxidation +Mg 0.3/Co-Fe-B 2/Ta 10/Cu-N 30/Ru-7 (thicknesses in nm). The stack was annealed for 90 min at 360 °C and cooled in a field of 1 T to establish the exchange bias. Using electron beam lithography and ion beam milling, the stack was patterned into elliptic tunnel junctions with different sizes from 600 nm × 250 nm to 260 nm × 120 nm. The zero bias TMR was between 45% and 160% and R × A (resistance-area product) between 3Ω × μm² and 19Ω × μm². Out of 13 MTJs with TMR at

while the negative bias direction would favor an AP alignment favors the P alignment, it will destabilize the AP alignment, the influence of spin torque on DW/MI. If the positive bias TMR in the AP state (Fig. 2(a)).

If the positive bias of electrons from the hard to the soft electrode (Figs. 2(a)).

(Fig. 1(b)), which has a RTN origin (further RTN1). Very strong increase of the noise power (Fig. 1(b)) is accompanied by a change in the resistance of less than 0.2%. Estimations show that changes of RTN1 with bias polarity (Fig. 1(b)) could be partially due to self-field.

To estimate the fluctuating magnetic moment (Δm), we have measured field and bias dependence of the ratio between inverse attempt transition rates12,13: τ1/τ2=exp(−2ΔmH/k_BT), τ1 and τ2 being the average time spent in each of two activated states. This relation considers the magnetization directions of fluctuating states being P-AP to the external field. Figure 1(c) shows typical histograms of RTN1 for magnetic field above and below the maximum of noise in P state. A linear fit of ln(τ1/τ2) vs. H (Fig. 1(d)) provides an estimation of the fluctuating moment of 1.5 x 10^7 μ₀m and within 10% being independent of the bias polarity up to 400 mV. We estimate that DW/MI occupy about 10% of the soft electrode area (with CoFeB moment per atom of 1 μ₀m). To account for maximum 0.2% variation of the resistance in the P state near RTN1, the related DW/MI should be located in the hard layer outside the MTJ stack.

The largest submicron MTJs (A = 0.0565 μm², 0.0675 μm²) do not show noise anomalies in the P state but reveal (Fig. 2(a)) a strong noise enhancement in the AP state at least 100 Oe above the AP-P transition, also originated from RTN (further RTN2). The investigation of the RTN2 time series as a function of magnetic field provides fluctuating moment of 4 x 10^7 μ₀m. New feature of the RTN2 is that it exists only with positive bias corresponding to the injection of electrons from the hard to the soft electrode (Figs. 2(a) and 2(b)). The MI/DWs, which originate RTN2, are probably located in the free electrode. Indeed, its estimated fluctuating area is about 7%, in rough agreement with 2% reduction of TMR in the AP state (Fig. 2(a)).

The absence of RTN2 for negative biases indicates possible influence of spin torque on DW/MI. If the positive bias favors the P alignment, it will destabilize the AP alignment, while the negative bias direction would favor an AP alignment of both electrodes and suppress RTN2. Unlike RTN1, fluctuations similar to RTN2 were seen in GMR nanopillars, but at current densities above 10^7 A/cm².

To estimate self-fields H_self-field, we assume circular nanopillars with uniform current density J. The surface integral of the J crossing surface σ equals the line integral of the self-field H_self-field along a contour, ∂σ: J dS = ∫_r H dJ. For a circular path ∂σ of radius r, this provides H_self-field = J / r² of few hundreds of Oe for GMR nanopillars. To verify this for RTN2, Fig. 3(a) compares estimated H_self-field with dependence of the soft layer coercive field (Hc) for the fields where resistance steps and RTN2 in the AP states are observed (H_self-field) both referenced to Hc at zero bias) as a function of J. This analysis rules out significant influence of self-field on RTN2. We further checked the effects of self-fields on RTN2 kinetics by attempting to compensate them with changes in magnetic field. Figures 3(b)–3(d) show that to compensate changes related to current with estimated variation of self-field below 2 Oe one should vary external field in about 30 Oe. This indicates that the effects of self-fields are not sufficient to explain the asymmetry in RTN2 kinetics.

A simple model qualitatively explains the possible origin of the RTN1,2 (Fig. 4). While the soft electrodes in the smallest MTJs remain in a single domain state, close to magnetization inversion the largest electrodes show for the same fields (independently of anisotropy as confirmed by simulations) DW/MI formation with a 7% reduction of the magnetization of the soft layer (Fig. 4(b)), which could provide RTN2. Formation of the small (10^5 μ₀m) DW/MI in the AP state could affect the current distribution (which is mainly of Δs symmetry for the ideal AP alignment creating “pseudo-pinhole” for electrons with Δt symmetry (Fig.

The RTN1 is most probably due to DW/MII located in the biased layer outside and close to the edge of the MTJ pillar (Fig. 4(a)). The origin of DW/MII could be 360° DWs (Ref. 28) pinned by the stray field of the soft layer (Fig. 4(a)). Figure 4(b) summarizes the characteristic magnetic fields where reproducible maxima of RTN(1,2) were observed. The absence of RTN1 in largest MTJs with reduced influence of the edge stray field (Fig. 4(b)) contradicts explanation the RTN1 due to defects in the MgO influenced by magnetostriction.

In summary, RTN measurements in submicron MTJs with dimensions close to the transition to the single domain regime revealed the presence of single magnetic inhomogeneities in the soft and hard layers. RTN fluctuations and related resistance steps in the AP state due to MI/DWs are asymmetrically influenced by the current which could be used to displace domain walls in the soft layer using relatively low current densities.
