9 **Abstract**

10 Mercury tolerance in wild vascular plants has hardly been studied and a tolerant ecotype  
11 is not known. In order to confirm the tolerance to Hg of *Rumex induratus* naturally  
12 growing in the biggest Hg mine in the world (Almadén population), the population was  
13 compared in a hydroponic experiment with another population from a non Hg-  
14 contaminated area (Colmenar). The plants were exposed to different doses of Hg and a  
15 dose of As to establish whether the tolerance to Hg coincides with tolerance to other  
16 trace elements. Plants from Colmenar reached up to 1322  $\mu\text{g Hg g}^{-1}$  in roots and 65  $\mu\text{g}$   
17  $\text{Hg g}^{-1}$  in shoots and showed a significant decrease of biomass due to Hg exposure,  
18 while Almadén accumulated only 812  $\mu\text{g Hg g}^{-1}$  and 56  $\mu\text{g Hg g}^{-1}$  respectively. The  
19 Almadén population showed a higher tolerance to intense exposure to Hg, but not to As.  
20 Plants from Almadén exposed to Hg showed higher capacity to synthesize thiols in the  
21 root and to control oxidative stress and Zn starvation. Our findings suggest that *Rumex*  
22 *induratus* could be used to enhance understanding of the mechanisms of Hg tolerance in  
23 plants.

## 2 **1. Introduction**

3 Mercury concentration in soils has increased due to human activities, some places  
4 therefore show levels far beyond background level of  $<0.15 \text{ mg Hg kg}^{-1}$  (Patra and  
5 Sharma 2000). Almadén (Ciudad Real, Spain) has the largest Hg mine in the world,  
6 where levels of up to  $10,000 \text{ mg Hg kg}^{-1}$  have been reported (Millán et al. 2006;  
7 Millán et al. 2011). Similarly, common levels of Hg in plants range from 0.001 to 0.1  
8  $\mu\text{g g}^{-1}$  (Veiga et al. 1994), but levels greater than  $10 \mu\text{g g}^{-1}$  have been detected in plants  
9 in Almadén (Millán et al. 2006). In such a Hg-contaminated site, plants have to  
10 compensate for the high levels of Hg by using physiological mechanisms similar to the  
11 response to other trace elements (Patra et al. 2004). In the case of other metal(loid)s, the  
12 studies of populations with different tolerance have helped to understand the  
13 physiological mechanisms implicated in metal tolerance: populations of *Thlaspi*  
14 *caerulescens* for Cd and Zn (Lombi et al. 2002), *Arabidopsis* spp. for Cu (Murphy and  
15 Taiz 1995), *Alyssum* spp. for Ni (Broadhurst et al. 2004, Marmioli et al. 2004), *Silene*  
16 spp. for Zn, Cd, Cu and As (Verkleij et al. 2001; Arnetoli et al. 2008) and *Holcus*  
17 *lanatus* for Cu and As (Hartley-Whitaker et al. 2001). However, there is no report about  
18 different ecotypes from a plant species with different tolerance to Hg. Recently, the only  
19 papers reporting plant cultivars with Hg tolerance have used rice or Indian mustard (Yu  
20 et al. 2011; Shiyab et al. 2009), but these cultivars were not growing naturally in Hg-  
21 enriched environments nor do we know about any potential of these particular plants for  
22 Hg soil phytoremediation. The identification of tolerant ecotypes among metallophyte  
23 populations and the understanding of physiological mechanisms of tolerance is a key  
24 research question in order to be able to implement phytoremediation of Hg-polluted  
25 soils (Verbruggen et al. 2009). Toxic effects of Hg in plants have been studied less

1 intensively than other elements (e.g. As, Ni, Cd), but some concepts are already well  
2 established: Hg at high doses induces oxidative stress; depletes chlorophylls; alters  
3 water fluxes; mineral nutrition; and plant development (Moreno-Jiménez et al. 2007,  
4 2009).  
5 Previously, a population of *Rumex induratus* from Almadén (Almadén ecotype) was  
6 identified as a potential phytoremediator of Hg-degraded soils where thiol and  
7 malondialdehyde (MDA) concentrations were related to Hg toxicity (Moreno-Jiménez  
8 et al. 2007). Therefore, the main objectives of this study, under controlled laboratory  
9 conditions, are firstly to determine the tolerance of *Rumex induratus* to Hg after the  
10 plant's long-term exposure in Almadén and secondly, to investigate its potential  
11 adaptation to high Hg concentrations, comparing its properties with that of a population  
12 which has no record of Hg exposure. Additionally, As phytotoxicity (Moreno-Jiménez  
13 et al. 2012) and the potential induced co-tolerance to As was also tested.

14

## 15 **2. Materials and methods**

### 16 *2.1. Seed collection*

17 Two populations of *Rumex induratus* Boiss & Reuter (Polygonaceae) were selected  
18 from areas with different historical Hg exposure. The first population was collected  
19 from a mine tailing in the Almadén district (38°43'37"N, 4°40'36"W, Ciudad Real, SW  
20 Spain), where Hg concentrations of up to 1000 mg kg<sup>-1</sup> were reported (Moreno-Jiménez  
21 et al. 2006). The other population was obtained from an agricultural plot in Colmenar  
22 Viejo (40°42'35"N, 3°46'04"W, Madrid, C Spain) with no previous Hg contamination  
23 reported. Mature seeds from both populations were collected and stored at 4°C with  
24 silica gel until germination.

### 25 *2.2. Plant culture*

1 Plant seeds were germinated in perlite moistened with distilled water and 1.5 mM  
2  $\text{CaSO}_4$  in darkness for 4 days at 28 °C. When the seeds were germinated, plants were  
3 maintained at 28 °C (16 h light, 8 h darkness) in distilled water for the first week and  
4 then control nutrient solution for the next three weeks to the substrate. The nutrient  
5 solution had the following composition (pH  $\approx$  6.5): 1.5 mM  $\text{KNO}_3$ , 1.5 mM  $\text{Ca}(\text{NO}_3)_2$ , 1  
6 mM  $\text{KH}_2\text{PO}_4$ , 1 mM  $\text{MgSO}_4$ , 0.75 mM  $\text{K}_2\text{SO}_4$ , 53.76  $\mu\text{M}$  Fe-EDDHA, 27.3  $\mu\text{M}$   
7  $\text{MnSO}_4$ , 0.32  $\mu\text{M}$   $\text{CuSO}_4$ , 0.77  $\mu\text{M}$   $\text{ZnSO}_4$ , 46.25  $\mu\text{M}$   $\text{H}_3\text{BO}_3$ , 0.016  $\mu\text{M}$   
8  $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}$ . After four weeks of growth, three to four seedlings were transferred to  
9 each plant pot (1.5 L). For three weeks all the plants were grown with control nutrient  
10 solution. For the final four weeks Hg treatments were added as  $\text{HgCl}_2$  in doses of 0, 5  
11 and 50  $\mu\text{M}$  Hg, whilst only one arsenic dose of 50  $\mu\text{M}$  was supplied as  $\text{NaH}_2\text{AsO}_4$ .  
12 Doses of Hg and As were chosen according to the results from previous hydroponic  
13 experiments (Moreno-Jiménez et al. 2007 and Moreno-Jiménez et al. 2009). Each  
14 treatment was replicated four times. Nutrient solutions were replaced at 7-day intervals  
15 throughout the experiment. The experiment was carried out in a growth chamber under  
16 the following environmental conditions: night/day (8h/16h) T 20–25 °C and relative  
17 humidity of 60–40%.

18 Plant exposure to Hg and As in treatments was assessed, showing a recovery higher  
19 than 70% with respect to the theoretical dose. Hg and As speciation in nutrient solutions  
20 was modeled using the software Visual MINTEQ version 2.53 and the predominant  
21 chemical species were predicted to be  $\text{Hg}^{2+}$  (more than 95% of mercury) and  $\text{H}_2\text{AsO}_4^-$   
22 (more than 75% of the total arsenic) based on the composition of the experimental  
23 solution.

24 *2.3. Sample processing and analysis*

1 At the end of the experiment, plants were harvested and divided into root, stem and  
2 leaves. All plant material was thoroughly washed with tap water followed by a  
3 subsequent rinse in distilled water for 2 min. Total fresh weight of each tissue was  
4 determined, then a representative 7 g aliquot was oven-dried to constant weight at 30°C  
5 for 7 days prior to preparation for elemental analysis. The remaining sample was frozen  
6 in liquid N<sub>2</sub> and stored at -70 °C for future use.

7 Dry plant material was acid digested using 4 mL of mili-Q water, 1.3 mL of HNO<sub>3</sub> and  
8 0.9 mL of H<sub>2</sub>O<sub>2</sub>, added to 0.2 mg dry weight (DW) sample. Material was digested  
9 under pressure at 1.5 kPas and 125 °C (Lozano-Rodríguez et al. 1995). Digests were  
10 filtered, then diluted to 15 mL with mili-Q water prior to As, Hg and Zn determination  
11 by ICP-MS (SIDI UAM, with ISO 9001). Certified reference material (CTA-VL2,  
12 tobacco leaves, 0.97 µg As g<sup>-1</sup>; and BCR 62, olive leaves, 0.28 µg Hg g<sup>-1</sup>) was used as a  
13 quality control of the method and found to contain 0.94 ± 0.06 µg As g<sup>-1</sup> and 0.27 ±  
14 0.01 µg Hg g<sup>-1</sup>.

15 Acid soluble thiols were extracted and determined following Jocelyn (1987): 0.1 g fresh  
16 weight (FW) was extracted with 0.4 mL of NaOH (0.1 M) + NaBH<sub>4</sub> (25 mg mL<sup>-1</sup>) and  
17 0.2 mL of distilled water, then centrifuged at 11,000 g for 5 min. The resulting  
18 supernatant (0.5 mL) was diluted with 0.2 mL HCl (35%) and centrifuged at 11,000 g  
19 for 5 min. Then 0.5 mL of DTNB 300 µM in phosphate buffer 0.5 M (pH = 7.5) were  
20 added to 0.5 mL of supernatant and heated at 30 °C for 2 min. Absorbance was  
21 determined at 412 nm. For correlation, GSH standards (0, 10, 20, 50, 100 and 150 nmol  
22 GSH) were used to fix the calibration curve.

23 Lipid peroxidation in plant tissues was based on an estimate of malondialdehyde  
24 (MDA) concentration, as described by Heath and Packer (1968). A 0.1g FW aliquot of  
25 tissue was extracted with 1 mL of colorimetric reactive TCA (15%) – TBA (0.37%) –

1 HCl (0.25 M), heated at 90 °C for 30 min and then cooled. After centrifugation at  
2 11,000 g for 10 min, the absorbance of supernatant was measured at 532 nm and 600  
3 nm. The extinction coefficient was  $1.56 \cdot 10^5 \text{ M}^{-1} \text{ cm}^{-1}$ .

#### 4 *2.4. Statistical analysis and data processing*

5 Data were processed with Microsoft Excel2007 and SPSS 15.0. Two-way ANOVA was  
6 used for mean comparison, with ecotype, Hg treatment and their interaction as factors.

7 The influence of Hg on plant biomass or MDA concentration was expressed as the  
8 relative increase (in percentage) induced by each Hg dose with respect to the same  
9 parameter in control plants of each ecotype. To determine the relationship between  
10 thiols and Hg concentration in tissues, Hg concentration was transformed to a fresh  
11 basis using the percentage of water.

12

### 13 **Results**

14 Plant biomass, both in roots and in shoots, was reduced in both populations of *R.*  
15 *induratus* by the exposure to Hg in the nutrient solution (Figures 1a,c, Supplementary  
16 Material for statistics). Although both populations showed only a slight decrease of  
17 biomass caused by 5  $\mu\text{M}$  Hg (<20% of reduction), in the case of 50  $\mu\text{M}$  Hg results  
18 differed for each population: while the Almadén ecotype experienced a moderate  
19 reduction of growth (slightly higher than 20%), the Colmenar population showed a  
20 sharp growth inhibition, up to 72%.. The Hg concentrations in the shoots and roots of *R.*  
21 *induratus* were in accordance with the level of exposure (Figures 1b,d, Supplementary  
22 Material for statistics). Slight differences were detected between ecotypes, the most  
23 noticeable a higher Hg concentration in roots of the Colmenar population.

1 In contrast to Hg results, Table SM2 (Supplementary Material) shows that 50  $\mu$ M As  
2 resulted in a higher growth reduction in the Almadén ecotype, whilst the Colmenar  
3 population did not suffer evident losses of biomass.

4 To test the damages induced by Hg in the two populations of *R. induratus*, MDA was  
5 used as an indicator of oxidative stress, and significant differences were observed  
6 (Supplementary Material). In both populations the concentration of MDA increased  
7 after a high exposure to Hg (50  $\mu$ M), both in roots and in shoots (Figures 2a,c). This  
8 increase was only slight in the Almadén ecotype (about 9-14%), but was very noticeable  
9 in the Colmenar population (60-158%), suggesting that Hg caused significant damage to  
10 the tissues of the latter.

11 Thiols concentration was another parameter selected to study differences in the response  
12 to Hg. In both populations the roots of *R. induratus* showed increasing concentration of  
13 thiols at higher exposures to Hg, but leaves did not show any clear tendency (Figures 2b  
14 and 2d). For roots, the Almadén ecotype showed a higher correlation between  
15 concentration of Hg and of thiols (0.83) than the population of Colmenar (only 0.20),  
16 indicating that Almadén ecotype has a more effective response to Hg.

17 Zinc concentration significantly varied between populations and in response to the level  
18 of Hg exposure (Figure 3). For the control treatment, *R. induratus* from Colmenar had  
19 the highest Zn concentration, but it decreased sharply in both roots and shoots upon Hg  
20 exposure, decreasing Zn levels up to 72% in shoots and 61% in roots. The population  
21 from Almadén showed more constant plant Zn concentration after exposure to Hg in the  
22 nutrient solution.

23

24 **Discussion**

1 The Almadén population showed a higher tolerance to Hg, suggesting that the long-term  
2 exposure to Hg in the habitat has allowed the plant to develop protective physiological  
3 traits. Hg inhibits plant growth at high exposures (Cho and Park 2000; Moreno-Jiménez  
4 et al. 2007, 2009; Wang and Greger 2004), and the growth of the Colmenar population  
5 decreased by 70%, whilst the Almadén ecotype showed only a moderate inhibition  
6 (about 20%). Similarly, the Colmenar population also experienced higher oxidative  
7 stress. Oxidative stress is the result of the presence of Hg at high concentrations, when  
8 antioxidant systems are saturated causing damage at the cellular level (Ortega-  
9 Villasante et al. 2005; Sobrino-Plata et al. 2009). The Almadén ecotype showed a better  
10 antioxidant response than the Colmenar one. The concentration of –SH groups in  
11 cytosol plays an important role to maintain cell homeostasis because GSSH can  
12 alleviate oxidative stress (Rellán-Álvarez et al. 2006) and also thiol enriched  
13 biomolecules (GSSH, phytochelatins) can complex Hg and reduce its activity (Krupp et  
14 al. 2008; Carrasco-Gil et al. 2011). Roots of *R. induratus* responded to Hg by  
15 synthesizing –SH. The Almadén ecotype also had higher ability to synthesise thiols,  
16 indicating a better protective response. However, in leaves, this mechanism does not  
17 seem to be as effective as in roots, in agreement with previous findings (Moreno-  
18 Jiménez et al. 2007). This may suggest thiol groups play a role in Hg detoxification in  
19 roots, but as both populations show to an increase of thiols, this mechanism is not  
20 enough to explain the large differences in Hg-tolerance between the two ecotypes of *R.*  
21 *induratus*. This lack of response of thiols in shoots may be explained if the pool of –SH  
22 in the aboveground tissues is enough to maintain the cell homeostasis and alleviate  
23 toxicity despite the accumulation of Hg. Calgaroto et al. (2011) have suggested recently  
24 that Zn may alleviate Hg toxicity, probably protecting plant tissue against oxidative  
25 stress. In our study, the population of Colmenar showed a severe decrease of Zn levels

1 in shoot and root, even at lower levels of Hg. However, the population of Almadén  
2 showed only very slight depletions of Zn upon exposure to high levels of Hg,  
3 suggesting again higher resistance than the population of Colmenar. Our work reports  
4 for the first time an ecotype of *R. induratus* with different tolerance to Hg, but this fact  
5 is not associated to a higher resistance to As. So the detoxification mechanisms in the  
6 Almadén ecotype are mainly effective for Hg. This opens the possibility of further  
7 research to investigate the plant mechanisms associated to Hg-tolerance: root uptake,  
8 Hg compartmentalization (cell wall, vacuole), Hg complexation and speciation (PCs,  
9 methylmercury), genes involved (AFLP, QTLs), and maintenance of cell homeostasis  
10 (antioxidant enzymes). For instance, AFLP fingerprinting has been used to compare  
11 populations of *Onosma echioides* from different locations (Mengoni et al., 2006), the  
12 role of certain plant alleles in Hg-tolerance have been reported in some crops (Shiyab et  
13 al. 2009; Yu et al. 2011) and PCs have been shown to play a primary role in Hg-  
14 detoxification after short exposure (Carrasco-Gil et al. 2011), but these hypotheses  
15 should be validated in natural Hg-tolerant ecotypes.

16

## 17 **Conclusion**

18 The development of our knowledge for other trace elements (As, Ni, Cd, Zn) has been a  
19 step ahead, but as a result of our study we suggest to use similar models to explore Hg-  
20 tolerance mechanisms in plants. Historical exposure to Hg in Almadén mine district has  
21 promoted a tolerant ecotype of *R. induratus*, less sensitive to growth inhibition and  
22 oxidative stress upon Hg presence in the nutrient solution. The tolerant ecotype from  
23 Almadén demonstrated useful traits to make it a candidate for remediation of Hg-  
24 polluted soils.

## 2 **Figure Captions**

3

4 **Figure 1.** Biomass (g FW) and mercury concentration ( $\mu\text{g g}^{-1}$  DW) in two populations  
5 of *Rumex induratus* (Almadén and Colmenar) exposed to different doses of Hg during 1  
6 month. a) and b) shoot; c) and d) root. Numbers in the figures are the percentages of  
7 relative reduction of biomass with respect to control plants, mean  $\pm$  SE ( $n=4$ ). Statistical  
8 analyses are shown in Table SM1 (supplementary material).

9

10 **Figure 2.** Malondialdehyde (MDA) concentration ( $\text{nmol MDA g}^{-1}$  FW) and correlation  
11 between thiol concentration ( $\text{nmol -SH g}^{-1}$  FW) and Hg concentration ( $\text{nmol Hg g}^{-1}$   
12 FW) in two populations of *R. induratus* (Almadén and Colmenar) exposed to increasing  
13 doses of Hg. a) and b) Shoot; c) and d) Root, mean + SE,  $n=4$ . The numbers in the  
14 figures on the left are percentage of relative increase of MDA with respect to the control  
15 plants. The right hand figures: \*\*\* $P < 0.001$ ; \*\* $P < 0.01$ ; n.s. non significant. Further  
16 statistical analyses are shown in Table SM1 (supplementary material).

17

18 **Figure 3.** Zinc concentration ( $\text{mg Zn g}^{-1}$  DW) in two populations of *Rumex induratus*  
19 (Almadén and Colmenar) exposed to different doses of Hg during 1 month. a) Shoot  
20 and b) Root. The numbers on top of the columns are the percentage of depletion (-) or  
21 increase(+) of Zn in Hg treatments, with respect to the levels in control plants, mean  $\pm$   
22 SE ( $n=4$ ).. Statistical analyses are shown in Table SM1 (supplementary material),
