Two-dimensional electron gases (2DEGs) at surfaces and interfaces of semiconductors are described straightforwardly with a one-dimensional (1D) self-consistent Poisson-Schrödinger scheme. However, their band energies have not been modeled correctly in this way. Using angle-resolved photoelectron spectroscopy we study the band structures of 2DEGs formed at sulfur-passivated surfaces of InAs(001) as a model system. Electronic properties of these surfaces are tuned by changing the S coverage, while keeping a high-quality interface, free of defects and with a constant doping density. In contrast to earlier studies we show that the Poisson-Schrödinger scheme predicts the 2DEG band energies correctly but it is indispensable to take into account the existence of the physical surface. The surface substantially influences the band energies beyond simple electrostatics, by setting nontrivial boundary conditions for 2DEG wave functions.

DOI: 10.1103/PhysRevB.94.115305

I. INTRODUCTION

Two-dimensional electron gases (2DEGs) occurring at surfaces of semiconductors have been studied for many years due to their rich phenomenology and extreme technological relevance [1–13]. The 2DEGs arise following subsurface confinement of conduction electrons caused by an electric field. A characteristic quasi-2D surface electronic structure (a set of 2D subbands) is then observed. Depending on the semiconductor doping the phenomenon may take the form of the charge accumulation or the charge inversion layer. A few crystals host native charge accumulation/inversion layers at their surfaces, notably InAs, CdO, InN, In2O3, and SrTiO3. In many other cases the layers can be intentionally engineered, using adsorbates. Analogous phenomena are found at many interfaces [14–20].

Theoretical modeling of the 2DEGs builds upon the assumption that the surface electrostatic potential is screened by a degenerate electron gas residing in a subsurface potential well. This is formulated as a 1D self-consistent Poisson-Schrödinger problem. The problem has been solved iteratively [21–24] and also using the modified Thomas-Fermi approximation (MTFA) [25–28]. These two strategies have been found equivalent [26,29]. Nonetheless, angle-resolved photoelectron spectroscopy (ARPES) studies of the 2DEGs band structure have evidenced that the subband energies are not described well by such models [3,6,7]. It has been then proposed that taking into account many-body interactions could resolve the problem [3]. However, these interactions are known to be negligible [23] at least in some of the problematic 2DEG systems. Thus today, nearly 50 years after the first experimental evidence of 2DEG [14], there is still no complete understanding of the 2DEG systems.

In the present paper we revisit the problem by combining experimental and theoretical studies. Experimental ARPES results and theoretical calculations within the above discussed Poisson-Schrödinger scheme, obtained for an InAs based 2DEG, are brought into harmony after considering adequate boundary conditions for the 2DEG wave functions at the surface. These boundary conditions are traced back to the nontrivial potential interpolation between the crystal and vacuum.

II. EXPERIMENTAL METHODS

We focus on InAs, as it is probably the best studied material showing native accumulation layers [1–3,9,10,30–32], having as well a large technical application potential [33–35]. The band bending at InAs surface depends on its orientation and reconstruction as well as on adsorbates [2,9,10,30,32,36–40]. We use sulfur treatment on the (001) surface in order to control the bending [41].

Our samples are nominally undoped, n-type InAs(001) wafers with a donor concentration of 3 × 1016 cm−3. Sputtering of the surfaces is avoided, as it produces many electrically active defects in the subsurface region [32,42]. The samples are treated with a HCl-iPA solution in 5N nitrogen atmosphere, rinsed by iPA, blown dry, and transferred to ultrahigh vacuum without being exposed to atmospheric air, then annealed to prepare In and As terminated surfaces [32,43]. A S2 beam is generated using an electrochemical cell [44,45]. The S-adsorbed surfaces are annealed in steps to increasingly higher temperature and their reconstructions are monitored using LEED. Most of ARPES studies are done using He Iα radiation, at 80 K. Variable photon-energy ARPES spectra are acquired at APE beamline at Elettra storage ring in Trieste (Italy).

We study a few differently reconstructed surfaces, prepared with S adsorption on both In and As-terminated InAs(001). Little is known about their atomic structures [39,46–48] but it is not crucial for our discussion, as only values of the total band bending explicitly enter the model under consideration. A very important observation is that, due to the relatively low processing temperatures [49,50], the doping density in the subsurface region remains unchanged for all samples studied.

*jj.kolodziej@uj.edu.pl
and equals that of the bulk. Thus unnecessary complications such as uncertain \( \Delta \) (see below for the definition) and unbound-charge screening effects are eliminated on the experimental level.

### III. EXPERIMENTAL RESULTS

The band diagram defining the parameters and conventions used throughout the paper is shown in Fig. 1. \( E_F \) is the Fermi level for which we assign the zero energy. The bulk electronic structure is represented by a depth dependent valence band maximum \( \text{VBM}(z) \) and conduction band minimum \( \text{CBM}(z) \). The band gap \( (E_g) \) is the difference between the two. At the temperatures relevant to our experiment (\( \sim 80 \) K) \( E_g \) is equal to 0.40 eV [51]. The \( E_F \) to \( \text{CBM}(\infty) \) distance is denoted as \( \Delta \). \( \Delta \) is calculated using standard formulas [52] and it is small (\( \sim 10 \) meV) for our samples. The total band bending is obtained as \( \text{BB} = -\text{VBM}(0) - E_g - \Delta \). Throughout this paper the variable \( z \geq 0 \) denotes the depth beneath the surface located at \( z = 0 \).

Our study shows that the 2DEG subbands on InAs are not well resolved (as in many earlier reports, see Ref. [53]) if the sample quality is not excellent—see the exemplary spectrum in Fig. 2(a). However, we limit our discussion to examples where the subbands are seen clearly, cf. Figs. 2(b)–2(d).
subbands are found isotropic, so there is no need to consider their azimuthal orientation.

In order to determine the BB value we notice that the VBM in InAs corresponds to the $\Gamma_8$ level, which is the top of the B8 bulk band [54]. When measured with normal emission, variable excitation energy ARPES, the B8 band reaches maximal value at 10 eV photon energy and again at 60 eV [see Fig. 3(a) and Appendix A], meaning that the bulk $\Gamma$ point is probed for these energies. We also notice that, for the In-terminated (001)InAs surface, there exists a nondispersing surface resonance (S1), clearly seen at photon energies of 14 and 16 eV, when it is separated from bulk bands. As seen in Fig. 3(a) VBM(0) and S1 coincide (at $-0.55$ eV). Thus, for the In-terminated (001)InAs surface one may also find the VBM(0) simply by studying the onset of the valence band. In order to determine the BB using He I$\alpha$ excited ARPES for other samples we find the surface independent reference, that is the apparent B7 band maximum [B7M(0)], see Fig. 3(b).

Based on the detailed studies of the clean In-rich InAs surfaces we find the difference in energy between the VBM(0) and B7M(0) as 3.30 eV. Then the BB values are found using the formula $BB = -B7M(0) - 3.30 eV - E_\Gamma - \Delta$ [see also Figs. 3(c) and 3(d)]. As seen in Fig. 3, surface resonances are present at the $\Gamma$ point, aligned with the VBM(0) to within accuracy of our measurements, both for clean and S-passivated InAs(001) surfaces. Similar results have been obtained before [28,32,55].

Based on the spectra shown in Fig. 2 one may extract a few numerical results including the energies corresponding to the subband minima ($E_i$) and Fermi wave vectors for the subbands ($k_{F_i}$), see also Fig. 1 for explanation. These results are given in Table I. Earlier studies (see for example Ref. [3]) have revealed that MTFA underestimates the binding energies corresponding to subband minima $E_i$. Our experimental data are similarly incoherent with the energy spectra calculated from the MTFA, see the case $\lambda \rightarrow \infty$ [i.e., $\arctan(\lambda) > 1$] in Fig. 4.

GaAs in several studies—see Ref. [56] and references therein. The renormalization is found not to exceed 100 meV, for the band gap renormalization is measured for degeneratively doped concentrations 10^{18}–10^{19} cm^{-3}. This is scaled with \( \lambda \), the maximum of the wave function amplitude and hence it is larger for \( \lambda > 0 \) than for \( \lambda = 0 \). The values of \( \lambda \) given in Table II are relatively small.

### IV. THEORETICAL FRAMEWORK

In order to explain such discrepancies King et al. [3] proposed that many-body interactions within the accumulation layers (neglected when using MTFA) cause a giant renormalization of the InAs band gap down to 0.1 eV, which reflects the experimental uncertainty. Corresponding experimental energies are indicated by horizontal lines (red online). For \( \arctan(\lambda) > 1 \) MTFA solutions are reached. The vertical line indicates the \( \lambda \) value for which the theoretical and experimental binding energies \( E_i \) match the most closely.

![Diagram](image)

**FIG. 4.** Calculated dependencies of the theoretical 2DEG subband minima on the parameter \( \lambda \) (points), for the case of BB = 0.58 eV. Thin solid lines show the binding energies for BB ± 50 meV, which reflects the experimental uncertainty. The renormalization is found not to exceed 100 meV, for the band gap renormalization is measured for degeneratively doped concentrations 10^{18}–10^{19} cm^{-3}. This is scaled with \( \lambda \), the maximum of the wave function amplitude and hence it is larger for \( \lambda > 0 \) than for \( \lambda = 0 \). The values of \( \lambda \) given in Table II are relatively small.

**TABLE II.** Evaluated energies of the subbands minima for 2DEG corresponding to the experimentally investigated band bending and related values of \( \lambda \). Additionally solutions corresponding to \( \lambda \to \infty \) are shown with the smaller numbers.

### V. DISCUSSION

Figures 5(a)–5(d) schematically illustrates how \( \lambda \) impacts ground-state solutions \( \psi \). For \( \lambda = 0 \) the maximum of the wave function is located at the origin, corresponding to a large negative potential energy \( \langle \psi | V | \psi \rangle \). As \( \lambda \) grows, the maximum appears at some distance from \( z = 0 \), decreasing the binding energies of the 2DEG electrons. Another important factor is the kinetic energy, which measures the variation of the wave function amplitude and hence it is larger for \( \lambda = \infty \) than for \( \lambda = 0 \). The values of \( \lambda \) given in Table II are relatively small and the resulting wave function amplitudes at the surface are significant. In agreement with this observation we have shown recently, using ARPES [32], that on a clean InAs(001) surface, 2DEG states acquire the periodicity of the surface reconstruction. This is an experimental evidence that the 2DEG wave function amplitudes may be large at the very surface. In
order to illustrate the characteristic length scale concerning the investigated problem an exemplary potential curve and corresponding wave functions are shown in Figs. 5(e) and 5(f).

Relation (2) is in fact a generalization of the so-far considered model. To see this, we write the basis of generalized eigenfunctions as \( \cos \left[ k z + \phi(k) \right] \). The phase factor \( \phi \) satisfies

\[
\cos \left[ \phi(k) \right] = -\text{sgn}(\lambda) \frac{k}{\sqrt{k^2 + \lambda^2}}.
\]

(3)

For small wave vectors \( k \to 0 \) the phase \( \phi \) approaches \(-\pi/2\), so \( \cos[kz + \phi(k)] \approx \sin(kz) \); \( \lambda = 0 \) is the only exception from the rule. It is also interesting to note that for shallow subbands, located less than 0.1 eV below \( E_F \), corrections to their minimal energies resulting from allowing different values of \( \lambda \) are not large, see Table II. Therefore our results agree with earlier calculations by Abe et al. [62], referring to such shallow subbands, despite the fact that the specific surface boundary condition, corresponding here to \( \lambda \to \infty \), has been only considered by Abe et al.

In the envelope wave function approximation the trigonometric functions on the semiaxis can be regarded as coming from the interference between the incoming and outgoing waves

\[
\frac{1}{2} \left( e^{ikz} + e^{-ikz + 2i\phi} \right) = e^{i\phi} \cos(kz - \phi),
\]

(4)

with the reflection coefficient equal to unity. The phase \( \phi \) is the only remnant of the reflection caused by a nontrivial potential far from the surface. The condition used so far is equivalent to \( \phi = \pm \pi \) and its rationale is given in the literature: “As the characteristic penetration length of the wave functions into the vacuum is very short, much shorter than the variation of carrier density in the space-charge region, it is a good approximation to impose the boundary condition that the wave function is equal to zero at the surface and thus that the carrier concentration tends smoothly to zero at the surface” [28]. No doubt, the electron wave function dies off outside the crystal. But, this does not mean that the the generalized wave functions have to be \( \sin(\cdot) \) functions. This is true only if the surface is modeled as a featureless, infinite potential step, see Appendix C.

The envelope wave function is an effective description of phenomena on large scales compared to the lattice constant. Thus, there is no unambiguous method to put the surface plane into the system. Furthermore, there is an about 1 nm wide zone at the surface corresponding to the reconstructed layers. In this zone the assumptions of the envelope approximation do not hold. So, the realistic model of 2DEG should include three regions: the vacuum region with negligible wave function density, the crystal bulk where free-electron approximation works well, and a transition zone where the potential interpolates between its vacuum and bulk values. We solve the electrostatic problem in the crystal bulk leaving \( \lambda \) as an effective parameter accounting for the transition zone properties. In Appendix C we discuss simple models illustrating these ideas.

VI. CONCLUSIONS

We have presented coherent experimental and theoretical studies on 2DEG band structure for a few differently reconstructed InAs(001) surfaces, treated as a model system. The surfaces has been carefully chosen to avoid experimental problems that are often present for the kind of spectroscopic studies done. Surface band bending values have been cautiously evaluated. Thus, the obtained experimental material provides a robust test of the applied theoretical concepts. We find that a simple one-electron Poisson-Schrödinger model explains the 2DEG band energies well, provided that the surface model is not oversimplified, i.e., proper boundary conditions on the 2DEG wave functions are imposed. We show that the conditions effectively describe the “skin-deep surface zone” (or the physical surface) and correspond to a nontrivial surface potential. Neglecting the “skin effect,” what has been overlooked so far, leads to heavily underestimated 2DEG band energies. For InAs we find this effect solely being able to reconcile the measured and calculated energy spectra. Therefore we think that many-body corrections may be not taken into account to first order, in the context of surface 2DEG in InAs, but they may be more pronounced for other materials. The skin effect is, in principle, present for any 2DEG system, so that our findings impact also the understanding and modeling of two-dimensional electron gases existing at surfaces and interfaces of other semiconductors and oxides. Thus, further work is required to understand rigorously all aspects of the 2DEG band structure.

The conduction band minimum corresponds to the hole bands as well as the donor density factor could be neglected. The universality of the model while for the investigated samples the hole bands as well as the donor density factor could be neglected). The conduction band minimum corresponds to the zero energy. The charge density accumulated in the conduction band reads

$$n_{cb} = \frac{1}{\pi^2} \int_0^\infty \frac{k^2 dk}{1 + \exp \beta [E_{cb}(k^2) - E_F + V(z)]},$$  \hspace{1cm} (B1)

where $\beta = 1/k_B T$ with $k_B$ denoting the Boltzmann constant, $T$ is the temperature, and $V(z)$ is the electrostatic potential multiplied by the electron charge. We use the $\mathbf{k} \cdot \mathbf{p}$ relation for the kinetic energy of the electrons

$$E_{cb}(k^2) = \frac{\hbar^2}{2m_e} k^2 + \frac{E_g}{2} \left( \sqrt{1 + 4P^2k^2} - 1 \right),$$  \hspace{1cm} (B2)

where $m_e$ stands for the free electron mass. $E_g$ is calculated from the Varshni parametrization [28]

$$E_g = 0.415 - \frac{2.76 \times 10^{-4} T^2}{83 + T},$$  \hspace{1cm} (B3)

where $T$ is given in Kelvin and the energy in eV, and

$$P^2 = \frac{3\hbar^2}{2m_e} \left( \frac{m_e}{m_{cb}} - 1 \right) \frac{E_g + \delta}{(3E_g + 2\delta)E_g},$$  \hspace{1cm} (B4)

$\delta$ stands for the spin-orbit coupling, here $\delta = 0.381$ eV. $m_{cb} = 0.024m_e$ denotes the electron effective mass in the conduction band. The formula for hole density reads

$$p_i = \frac{1}{\pi^2} \int_0^\infty \frac{k^2 dk}{1 + \exp \beta [E_F + E_R - V(z)]},$$  \hspace{1cm} (B5)

where $i \in \{lh, hh\}$ stands for light and heavy holes, respectively. The numerical values of the hole masses are 0.021$m_e$ and 0.41$m_e$, respectively. The density of (positively) ionized donors in nondegenerate semiconductors reads

$$\bar{p}_d = \frac{N_B}{1 + 2 \exp \beta [E_F + E_R - V(z)]},$$  \hspace{1cm} (B6)

where the considered donor density is $N_B = 3 \times 10^{16}$ cm$^{-3}$ and the energy of shallow donors is denoted with $E_R$. However, the average distance between the doping atoms is $N_B^{-1/3} = 32$ nm, while the Bohr radius of the hydrogenic shallow donor states yields 35 nm. So, at this density the material is rather a poor metal [60], and a full donor ionization should be assumed,

$$p_d = N_B.$$  \hspace{1cm} (B7)

The electron neutrality condition for $V = 0$,

$$p_{lh} + p_{hh} + p_d - n_{cb} = 0,$$  \hspace{1cm} (B8)

sets the Fermi level. It is found 14 meV above the conduction band minimum.

Having set the Fermi energy, we can solve the Poisson equation

$$\frac{d^2}{dz^2} V(z) = \frac{\epsilon_0^2}{\epsilon_B \epsilon_0} [p_{hh}(z) + p_{hh}(z) + p_d(z) - n_{cb}(z)],$$  \hspace{1cm} (B9)

where $\epsilon_0$ and $\epsilon_B$ stand for the vacuum dielectric constant and InAs static dielectric constant, respectively, and $e_0$ for the electron charge. We require that $V(0)$ be equal to the measured band bending and that $V(z)$ vanish in the bulk ($z \to \infty$). Hence, the derivative of $V(z)$ at the surface, which

---

**APPENDIX A: DETERMINATION OF VBM(0)**

This Appendix is intended to assist the interpretation of the spectra shown in Fig. 3(a). Four parts of Fig. 6 show angle-resolved photocurrent maps measured using different photon energies. The two top maps correspond to 10 and 60 eV photon energies for which the bulk $\Gamma$ point is probed. For these maps the valence band region is dominated by bulk bands B8 and B7 and the VBM may be directly read as the energy of the B8 band at $k_{||} = 0$. In contrast, the two bottom maps correspond to 14 and 16 eV photon energies and illustrate the situation when the B8 band is seen away from the VBM. In these cases the valence band region is dominated by surface resonances, including the indicated S1 coinciding, at $k_{||} = 0$, with the VBM.

**APPENDIX B: CALCULATION SCHEME**

Here we outline the calculation procedure in detail. As the numerical procedures involved are not recourse demanding we take into account the following bands: light holes, heavy holes, conduction band, and donor density (this is done for the universality of the model while for the investigated samples the hole bands as well as the donor density factor could be neglected). The conduction band minimum corresponds to the

---

**FIG. 6.** ARPES photocurrent maps (second derivative) along $\Gamma'J'$ for 10 and 60 eV (top) and for 14 and 16 eV (bottom) photon energy. The maps are collected for the InAs crystal terminated with clean In-rich (001) surface, reconstructed $c(8 \times 2) - 4 \times 2$. Energy is measured relative to the Fermi level.
is interpreted as the surface charge, is not a free parameter. 
Now we can solve the Schrödinger equation:

$$E_{cb} \left[ -\frac{d^2}{dz^2} + V(z) \right] \psi = E \psi , \quad \text{(B10)}$$

where $E_{cb} \left( -\frac{d^2}{dz^2} \right)$ accounts for the nonparabolic dispersion relation. Various boundary conditions are assumed, as discussed in Sec. IV. Note that in Sec. IV we discussed the parabolic dispersion relation while the actual calculations are performed for nonparabolic $E_{cb}(k)$. The rationale is that the theory of Hamiltonian operators and related self-adjoint extensions on the semiaxis has been formulated for the Laplace operator. The status of the nonparabolic operators is not clear and our arguments lose their mathematical rigor. However, they seem to be physically reasonable as discussed in Sec. V and below.

The above described scheme is not fully self-consistent. When calculating potential (B9), the plane wave approximation is assumed. This potential is subsequently used to pick out the correct boundary condition. Numerical investigations showed that the choice of boundary condition is not decisive for the potential. It is $\frac{d}{dz} V(0)$ which is sensitive to $\lambda$, making us reluctant to attribute to it the strict physical meaning of the surface charge density.

**APPENDIX C: TENTATIVE INTERPRETATION OF $\lambda$**

We argue above that the nontrivial boundary condition imposed on the wave functions are due to the thin interpolation zone between the crystal and vacuum. To be more specific, we discuss below three simple models and show how these intuitions can be quantified. Here, to avoid technical complications, we consider the parabolic dispersion. We begin with the well known step potential

$$\Theta(z) = \begin{cases} \frac{\hbar^2}{2m} \Theta_0, & z < 0, \\ 0, & 0 > z, \end{cases} \quad \text{(C1)}$$

with $\Theta_0 > 0$. The Schrödinger equation has the form

$$\left(-\frac{\hbar^2}{2m}\frac{d^2}{dz^2} + \Theta(z) - \frac{\hbar^2}{2m} k^2 \right) \psi(z) = 0 , \quad \text{(C2)}$$

where $\frac{\hbar^2}{2m} k^2$ denotes the energy. The solutions read

$$\psi(z) = \begin{cases} \sin \left[ \phi_1(k) \right] \exp \sqrt{\Theta_0 - k^2 z}, & z < 0, \\ \sin [k z + \phi_1(k)], & z > 0. \end{cases} \quad \text{(C3)}$$

The phase

$$\tan \phi_1(k) = -\frac{k}{\sqrt{\Theta_0 - k^2}} \quad \text{(C4)}$$

ensures equality of the derivatives calculated at $0^+$ and $0^-$. For small $k$ the above equation simplifies to

$$\phi_1(k) = \frac{k}{\sqrt{\Theta_0}} , \quad \text{(C5)}$$

The nontrivial phase appears in the case of the step potential, it is negligible if $\Theta_0 \gg k^2$, so it holds only in the case of the infinite barrier. The interpolating zone can be introduced by an additional step

$$\Theta(z) = \begin{cases} \infty, & z < 0, \\ \frac{\hbar^2}{2m} U, & 0 < z < z_0, \\ 0, & z > z_0. \end{cases} \quad \text{(C6)}$$

We solve the Schrödinger equation (C2) for $0 < k^2 < U$ with the boundary condition $\psi(0) = 0$. The solutions read

$$\psi_+(k; z) = \begin{cases} a_+ \sinh \left( \sqrt{U - k^2} z \right), & 0 < z < z_0, \\ \cos (k z + \phi_+), & z > z_0, \end{cases} \quad \text{(C7)}$$

where $a_+$ and $\phi_+$ are parameters to be determined. The continuity of $\psi_+$ and its first derivative at $z_0$ result in the following relation for $\phi_+$:

$$\sqrt{U - k^2} \coth \left( \sqrt{U - k^2} z_0 \right) = -k \tan (k z_0 + \phi_+), \quad \text{(C8)}$$

leading for small $k$ to the following formula:

$$\cos \phi_+ = -\frac{k}{\sqrt{U^2 + k^2}} , \quad \text{(C9)}$$

with

$$k_+ = \sqrt{U} \coth \sqrt{U} z_0 \quad \text{(C10)}$$

and

$$a_+ = -\frac{k}{\sqrt{U \cosh \sqrt{U} z_0}} . \quad \text{(C11)}$$

Equation (C9) coincides with Eq. (3) upon identification $\lambda = k_+$ which allows drawing an analogy between low-energetic scattering from a nontrivial potential and the abstract condition (2) for $\lambda > 0$. The approximate value of the solutions is evident—the resulting wave functions have a common part $\sinh \sqrt{U} z$ on the distance $0 < z_0$. The matching condition is an approximate one and so are the resulting wave functions. But only this assumption allows switching to the well-defined but simpler Hamiltonian. To this end we consider the potential

$$V(z) = \begin{cases} \infty, & z < 0, \\ \frac{\hbar^2}{2m} U + v(z), & 0 < z < z_0, \\ v(z), & z > z_0. \end{cases} \quad \text{(C12)}$$

The potential $v(z)$ varies slowly on distances much larger than $z_0$. Additionally, we consider $U \gg v(z)$ for $(0,z_0)$, so that the solutions (C7) are valid for $z < z_0$. Then we arrive at the equation

$$\left(-\frac{\hbar^2}{2m}\frac{d^2}{dz^2} + v(z) - \frac{\hbar^2}{2m} k^2 \right) \psi(z) = 0 \quad \text{(C13)}$$

for $z > z_0$ and with the boundary condition $\psi'(z_0) = k_+ \psi(z_0)$. As a consequence, we obtain an approximate spectrum of the problem (C12), whose quality depends on the mutual relations between $U$ and $v$. Such a separation of problems for $z < z_0$ and $z > z_0$ is possible in the low energy region only.

Similarly, one can treat the case with $U < 0$. Then both $\lambda > 0$ and $\lambda < 0$ can appear. The latter case corresponds to the model with short-ranged potentials deep enough to produce a single bound state [61].

We limit our discussion to the low-energy sector. This is meaningful, if $k^2 \ll U$, i.e., the energy of the wave is much
The models above show that the penetration length through a barrier and the phase shift are not tightly related and any value of \( \lambda \) in Eq. (2) is admissible provided the existence of a short-ranged potential interpolating between the crystal bulk and the vacuum.

\[ f(z) = 1 - \frac{1}{2} (e^{-z} + e^{-z}) \]  
(C14)

which linearly approaches zero at the origin \([f(z) \sim z/2 \text{ for } z \to 0]\) and tends to a nonzero value for large \( z \) \([f(z) \to 1 \text{ for } z \to \infty]\). Using this function we define the potential

\[ W(z) = \frac{\hbar^2}{2m f(z)} \frac{d^2 f(z)}{dz^2} \]  
(C15)

that explodes close to the origin \([W(z) \sim +z^{-1} \text{ for } z \to 0]\) and quickly vanishes for large \( z \), see Fig. 7. Trivially, by plugging \( k = 0 \) and \( \psi = f \) into Schrödinger equation

\[ \left[ -\frac{\hbar^2}{2m} \frac{d^2}{dz^2} + W(z) - \frac{\hbar^2 k^2}{2m} \right] \psi(z) = 0 \]  
(C16)

one can check that \( f \) is a bound, zero-energy solution. It is called zero or threshold resonance [63]. The relevance of \( f \) lies in the fact that solutions with the same boundary condition \([\psi(0) = 0] \text{ approach (pointwise) } f(z) \text{ in the limit } k \to 0 [64]\). So, the low energy solutions are nearly constant in the region where \( f \) is constant and, in this region, appear as \( \cos(\cdot) \) functions, see Fig. 7 for a schematic explanation. As such, even \( \lambda = 0 \) can concur with the finite penetration length.

\[ W(z) \sim z^{-1} \text{ for } z \to 0 \]  
(C16)

lower than the barrier height. In physical terms, the barrier corresponds to the material work function (4–5 eV) which is at least ten times more than energies encountered in accumulation layers. There is also a term \( k z_0 \) in (C8) which is neglected to arrive at Eqs. (C9)–(C11). As such, the approximation works well if the surface potential range is small compared to the wave vectors \( k \).

The step functions are nonphysical. Now we will consider a model with a smooth potential \( W \) exploding to infinity for \( z = 0 \). The model has an interesting property: the wave functions vanish at the origin and, nevertheless, they are very close to \( \cos(\cdot) \) functions in the region where \( W \) is negligible. As such, the parameter \( \lambda \) considered above and the behavior of the wave functions at the very surface are not correlated. We consider function \( f \),

\[ f(z) = 1 - \frac{1}{2} (e^{-z} + e^{-z}) \]  
(C14)
The sulfur treatment allows us to keep ARPES images of 2DEG bands notably clear. The sulfur atoms are included in surface reconstructions to form a uniform (ordered) distribution of electrically active centers. This is in contrast to the case of adsorbed alkali atoms (forming chains and islands on the surface), which cause spatially nonuniform band bending and a distorted subband structure. Moreover, the surface disorder has a detrimental effect on ARPES spectra via scattering photoelectrons in their final states.

[53] Clear 2DEG subbands images have been obtained for CdO, in Refs. [5] and [3]. For both experiments the ∆ value is about 0.2 eV and its uncertainty must be also substantial. The case of InN in Ref. [8] is not interpretable because of undefined doping levels due to ion beam annealing treatment. For As(111), InN, InO, and SrTiO the obtained 2DEG structure images contain “pockets” filled with a signal in addition to (or even instead of) regular subbands.

Band gap reductions (BGN) due to the many-body interactions in electron-hole plasmas on weakly polar systems, for interparticle distance \( r_s \) relevant to the case discussed here (i.e., \( r_s \) within the range 0.1–0.5 when expressed in effective Bohr radius units) may be (rather roughly) extrapolated based on the results shown in the paper by G. Tränkle, H. Leier, A. Forchel, H. Haug, C. Ell, and G. Weimann, Phys. Rev. Lett. 58, 419 (1987). The result is several meV for the 3D case and <50 meV for the strict 2D case. Similar values (<50 meV for the 2D case) may be estimated based on the work by Das Sarma, Jalabert, and Yang [Phys. Rev. B 39, 5516(R) (1989)]. This work, however, indicates also that for the quasi 2D case (what is our case) the BGN is reduced as compared to the strict 2D case. This reduction is very significant already for the plasma layer thickness corresponding to the 0.25 Bohr radius. While both papers above are not strictly relevant, since they concern the electron-hole plasmas, nevertheless the estimations of the relative 2D/3D BGN should be applicable.
