SARS-CoV-2 infection causes an abrupt response by the host immune system, which is largely responsible for the outcome of COVID-19. We investigated whether the specific immune responses in the peripheral blood of 276 patients were associated with the severity and progression of COVID-19. At admission, dramatic lymphopenia of T, B, and NK cells is associated with severity. Conversely, the proportion of B cells, plasmablasts, circulating follicular helper T cells (cTfh) and CD56–CD16+ NK-cells increased. Regarding humoral immunity, levels of IgM, IgA, and IgG were unaffected, but when degrees of severity were considered, IgG was lower in severe patients. Compared to healthy donors, complement C3 and C4 protein levels were higher in mild and moderate, but not in severe patients, while the activation peptide of C5 (C5a) increased from the admission in every patient, regardless of their severity. Moreover, total IgG, the IgG1 and IgG3 isotypes, and C4 decreased from day 0 to day 10 in patients who were hospitalized for more than two weeks, but not in patients who were discharged earlier. Our study provides important clues to understand the immune response observed in COVID-19 patients, associating severity with an imbalanced humoral response, and identifying new targets for therapeutic intervention.

Introduction

Novel coronavirus disease (COVID-19), due to severe acute respiratory coronavirus 2 (SARS-CoV-2), is either asymptomatic or presents with mild symptoms in a majority of individuals. However, up to 20% of patients develop a severe form of the disease with pneumonia, which in some cases results in acute respiratory distress syndrome (ARDS) and requires invasive mechanical ventilation. ARDS, together with myocardial damage, are the main causes of mortality in COVID-19 [1].

A pathogenic hallmark of ARDS is the disruption of the alveolar-capillary barrier and a subsequent increase in permeability, which has been partially attributed to a maladaptive immune response. Thus, lung alveolar macrophages may be infected by the virus and become activated, leading to a cytokine release syndrome, which contributes to endothelial injury with the recruitment and activation of innate and adaptive immune cells and the extravasation of plasma components of the humoral immunity [2].

Humoral immunity plays a key role in the initial control of viral infections and cell-to-cell spread. It is mediated by the complement system and the immunoglobulins (Ig) [3, 4]. Different SARS-CoV-2 components such as pathogen-associated molecular patterns (PAMPs) and N protein, together with C reactive protein (CRP) from plasma, may activate either the alternative or the lectin pathways of the complement cascade early during infection [5]. Furthermore, early IgM isotype antibodies efficiently trigger the classical complement cascade. Secreted IgA antibodies neutralize viruses within the mucosa of the respiratory and gastrointestinal tracts. Finally, in a more advanced stage of the disease, virus-specific IgG antibodies opsonize viral particles. This may lead to the formation of immune complexes that contribute to the activation of the classical complement pathway. Furthermore, opsonized viral particles can attach to Fc receptors on phagocytes and NK cells. The latter constitute major innate immune mediators during antiviral responses, since they kill infected cells through different mechanisms, including antibody-dependent cell cytotoxicity (ADCC), which is mediated by the FcyRIIIA (CD16) binding to clustered IgG displayed on the cell surface of virally infected cells [6]. Isotype switching and affinity antibody maturation, as well as the generation of memory B cells and long-lived plasma cells, are B cell responses driven by helper T cells, in particular follicular helper T cells (Tfh).

However, the deregulated humoral immune response can damage host tissues. Complement-mediated tissue injury is elicited by an intense inflammatory loop secondary to C3a- and C5a-mediated recruitment and activation of neutrophils, monocytes, macrophages, lymphocytes, and platelets. Phagocytes in turn generate ROS and proteases, and neutrophils release neutrophil extracellular traps (NETs), which exacerbate tissue damage [7–10].

Several studies on SARS-CoV-2 infection have attempted to elucidate phenotypic features of immune cell subsets either associated with severity or predictive of disease outcome. However, these studies have been conducted, in most cases, with a limited number of patients, and clinical parameters and disease severity are not homogeneously recorded in all of them [11,12]. Likewise, although specific antibodies and complement activation have been proposed to mediate some of the most severe complications of coronavirus infections, including that of SARS-CoV-2 [2,5,13,14], solid evidence on the role of humoral immunity effector mechanisms in the pathogenesis of SARS-CoV-2-associated ARDS is clearly needed.

Results

COVID-19 patients have increased B cells and plasmablasts in peripheral blood

Our cohort of COVID-19 patients included 276 SARS-CoV-2 infected individuals who were further classified according to the severity of their clinical signs and symptoms in mild, moderate, and severe, following recently described criteria [15]. The mean duration of symptoms before admission was 7.36 ± 5.2 days. Table 1 shows the main demographic and laboratory characteristics. The median (percentile 25 and 75) age was 63 (53.25–75) and 163 (59.05%) were men.

We conducted an initial analysis following the COVID-19 admission protocol, which comprised the quantification of the main peripheral blood lymphocyte subsets, including T, B, and NK lymphocytes as well as plasmablasts, by multiparametric flow cytometry (Fig. 1A, Suppl. Fig. S1). The proportion of T lymphocytes (either CD4+ or CD8+) and NK cells was similar in all the patients and healthy volunteers, with the exception of CD8+ T cells, which decreased in severe patients (Fig. 1B). Conversely, the percentage of B cells was higher in COVID-19 patients and increased with disease severity, raising from a mean of 9.15% in healthy donors to 20.49% in severely ill patients. In accordance, plasmablasts were remarkably higher in patients, both in relative and absolute values (mean 1.51% vs 17.98%; and 2.83 cells/μl vs 27.37 cells/μl, respectively), and regardless of severity degree (Fig. 1B). This increase in absolute plasmablasts number is of special relevance, given the lymphopenia present in COVID-19 patients (Table 1), and the diminished absolute number of other lymphocyte subsets (Fig. 1B). The elevated number of plasmablasts suggested a redistribution of the main maturation stages of the B lineage, including naïve, transitional, unswitched memory, IgM-only memory, and class-switched memory B-cells, which were identified in a subgroup of 84 patients from our initial cohort, with the gating strategy shown in Supporting Information Fig. S2. In COVID-19 patients, the proportion of IgM-only memory B-cells increased, while unswitched memory cells decreased (Fig. 1C). This redistribution was more marked in mild patients and progressively diminished in moderate and severe patients. Nevertheless, differences among patients with different severity degree were not statistically significant (Suppl. Fig. S3).

Increased follicular helper T cells in the peripheral blood of COVID-19 patients

Given the role of Tfh in maturation and activation of B cells, we assessed whether circulating Tfh (cTfh) were increased in the peripheral blood of COVID-19 patients, in accordance with the increased number of plasmablasts. We observed that the cTfh proportion significantly increased with the severity of COVID-19 individuals, shifting from a median of 0.51% in healthy donors to 1.7% in severely ill patients. Importantly, the absolute number remained steady despite the profound decrease of total CD4+ T cells (Fig. 2A, Fig. 1B). To further characterize this population, we assessed the surface expression of CCR7 chemokine receptor, which has been related to lower B-cell activation capacity by Tfh [16, 17]. We found a significant increase in CCR7 expression in cTfh cells of patients with moderate to severe disease (Fig. 2A). Finally, we found a direct correlation between cTfh proportion and total B-cells (r 0.33; p = 0.0090), class-switched B-cells (r = 0.26, p = 0.0433), and plasmablasts (r = 0.33, p = 0.0091) in peripheral blood (Fig. 2B).

COVID-19 severity associates to serum levels of immunoglobulins and complement

The high number of plasmablasts prompted us to investigate possible alterations in Ig concentrations. At the time of admission, COVID-19 patients had serum concentrations of either IgG, IgA, or IgM isotypes comparable to those in healthy volunteers (Fig. 3A). On the other hand, when patients with different degrees of severity were analyzed, we observed that, in severe cases, the levels of IgA and IgM were similar, but the IgG concentration was decreased, compared to healthy volunteers (Fig. 3B). In addition, a direct correlation was found between IgG (0.37; p = 0.0007)
and IgA (0.23; \( p = 0.0444 \)) serum concentrations and the absolute number of plasmablasts in peripheral blood, and between IgM levels and total number of peripheral blood IgM-only memory B-cells (0.36; \( p = 0.0040 \)) in COVID-19 patients. On the contrary, IgG (-0.31; \( p = 0.0147 \)) and IgA (-0.38; \( p = 0.0021 \)) were inversely related to the proportion of unswitched memory B cells (Fig. 2B).

The increase in plasma concentrations of IL-6 and acute phase reactants that characterizes COVID-19 (Table 1) suggested that
Figure 2. Circulating Tfh lymphocytes are increased in COVID-19 patients. (A) Left: Boxplots show quantification by multiparametric flow cytometry of cTfh lymphocytes as percentage or absolute number (cells/μl) in healthy donors (n = 19) and selected COVID-19 patients with different severity degree (mild (n = 29), moderate (n = 40), and severe (n = 15)). Right: Boxplots show CCR7 MFI of cTfh lymphocytes in healthy donors and COVID-19 patients with different severity degree (mild, moderate, and severe). Boxplots display percentiles 25 and 75 and median, and the whiskers correspond to percentiles 5 and 95. Asterisks indicate significant differences (p-values for ANOVA Tukey’s contrast test: *p < 0.05, **p < 0.01, ***p < 0.001, ****p < 0.0001). (B) Annotated heatmap of a correlation matrix for different variables in those same COVID-19 patients (n = 84). White squares include non-significant correlations (p > 0.05), red and blue squares include significant indirect and direct correlations (p < 0.05), respectively. Numbers inside squares and intensity of color correspond to Spearman’s rank correlation coefficient. Variables in the correlation map were reordered using the hierarchical cluster method. Data are from 19 experiments, with a median of 6 patients per experiment and day. MBC = memory B cells.
Figure 3. Immunoglobulins and complement levels are altered in COVID-19 patients. (A) Quantification of serum concentration (mg/dl) by nephelometry of IgG, IgA, IgM, C3, and C4 in healthy donors (n = 19) and COVID-19 patients (n = 255), and C5a by ELISA in healthy donors (n = 10) and COVID-19 patients (n = 63). (B) Serum concentration (mg/dL) of IgG, IgA, IgM, C3, and C4 in healthy donors (n = 19) and COVID-19 patients according to severity degree (mild (n = 138), moderate (n = 82), and severe (n = 35)). Serum concentration (ng/ml) of C5a in healthy donors (n = 10) and COVID-19 patients according to severity degree (mild (n = 29), moderate (n = 19), and severe (n = 15)). Values represent quantification for each serum marker depicted as boxplots. Asterisks indicate significant differences (p-values for Mann–Whitney t-test or ANOVA Kruskal–Wallis test, as appropriate: *p < 0.05, **p < 0.01, ***p < 0.001, ****p < 0.0001). Data are from samples collected over a 6 weeks period and analyzed within 24 h before freezing the serum. For C5a measurements, samples were thawed and assessed in two independent experiments. Box plots depict percentiles 25 and 75 and the median, and the whiskers show percentiles 5 and 95.
the concentration of C3 and C4 complement proteins, considered as acute phase reactants, could also be elevated. Therefore, we measured C3 and C4 levels in the sera of these patients, and could detect increased levels of both complement proteins (Fig. 3A). Accordingly, to investigate whether complement activation occurs in COVID-19 patients, we quantified C5a, the activation peptide of complement component C5, which showed increased plasma levels in most patients (Fig. 3A).

However, when considering different groups of severity, we observed that C3 and C4 levels increased in patients with mild to moderate disease, while returned to levels similar to healthy donors in those with severe disease (Fig. 3B). Therefore, in contrast to other inflammatory parameters such as LDH, ferritin or CRP (Table 1), C3 and C4 values decreased as the severity increased. Of note, unlike C3 and C4, C5a levels remained elevated in plasma regardless degree of severity (Fig. 3B).

Next, we tested whether the decrease in these components of humoral immunity was actually related to the severity of the disease in critical patients, or rather mirrored an increased consumption along time. We then considered a hospitalization period longer than 15 days as a readout of the severity of the disease and collected the blood of a subgroup of 37 COVID-19 patients who were still hospitalized 10 days after admission and compared it to the initial blood test. With this approach, we observed that antibodies of the IgG, IgA, and IgM isotypes, the IgG subclasses IgG1, IgG3, and IgG4 as well as C3, C4, and C5a complement proteins were similar in all patients at the time of admission (Figs. 4A and 4B). However, after 10 days, serum concentration of IgG was significantly lower in patients hospitalized longer than 15 days, whereas levels of IgA and IgM did not change over this time. Interestingly, whereas IgG1 and IgG3 levels showed a significant fold decrease in long versus short-stay patients after 10 days from admission, IgG4 concentration diminished similarly in both groups of patients. In order to determine whether these changes corresponded to a specific anti-SARS-CoV-2 response, we quantified IgG against SARS-CoV-2 RBD and N proteins, which could be detected at a high titer at day 10 in all cases (Supporting Information Fig. S4). On the contrary, anti-CMV IgG levels decreased after 10 days of hospitalization in both groups (Supporting Information Fig. S4).

Regarding complement, C3 serum levels were stable over time in both groups of patients. On the other hand, a significant decrease of C4 concentration was observed after 10 days specifically in those patients whose severity eventually required a longer stay (Fig. 4A). These patients however showed sustained C5a levels at this time point (Fig. 4A). Conversely, activation product C5a decreased in patients who stayed less than 15 days, which did not show a parallel C4 significant reduction (Fig. 4A).

The decrease in C4 and IgG serum concentrations in severe COVID-19 cases led us to hypothesize that antigen-antibody complexes were forming in excessive amounts and activating the classical pathway of the complement system. Therefore, we quantified immune complexes by enzyme immunoassay in the serum of the SARS-CoV-2 infected individuals with different levels of severity, but we did not find detectable levels (data not shown).

Phenotypic features of NK cells from severe COVID-19 patients

The decrease of IgG that characterized severe patients also suggested a possible role of ADCC, which has been described to be mediated by specific NK cell subsets [18]. We therefore quantified the main functional subsets of NK cells (CD56dimCD16+, CD56BrightCD16−, CD56−). A twofold increase in the proportion of CD56 CD16+ NK cells was found in severe COVID-19 patients compared to healthy donors and patients with mild disease (Fig. 5A). Furthermore, the absolute values of this population remained similar to those of healthy donors in all COVID-19 patients, in contrast to the decrease seen for other lymphocyte populations (Fig. 5A). Further analysis of this population showed significant downregulation of CD16 expression irrespective of the degree of severity (Fig. 5B). Interestingly, CD16 level in CD56 CD16+ cells slightly correlated to the serum concentration of IgG in COVID-19 patients (r = -0.24; p = 0.0496; Fig. 2B).

Discussion

It has been proposed that the severity of COVID-19 is related to a dysregulation of the immune response to SARS-CoV-2. However, there is no precise knowledge of the immune profile of COVID-19 patients with different clinical courses. To address this issue, we have performed a comprehensive characterization of the immune cell populations and soluble mediators of the humoral immunity in the peripheral blood of 276 patients, who presented from mild to critical illness in a single center during the peak of the pandemic in Madrid, Spain.

Plasmablasts were significantly elevated in the peripheral blood of most COVID-19 patients at the time of admission. In contrast, Ig levels were similar to those of healthy donors or even decreased in the case of IgG in critically ill patients. Since patients were studied at admission, it was feasible that Ig production had not peaked yet. However, IgG levels further decreased 10 days after admission in patients with longer hospital stays, which suggests that IgG decrease was rather related to severe disease progression. Three possible explanations may account for these apparently contradictory observations. The first explanation is a primary antibody immunodeficiency that debuts with COVID-19. This is supported by the fact that several patients had very low levels of IgG, IgA, and IgM in serum both at admission and after 10 days. We have not addressed this possibility yet, however, we plan to carry out studies aimed at verifying this hypothesis by assessing Ig levels three months after discharge. Second, it is possible that certain individuals show impaired specific Ig production (as might appear from the decrease of the titer of CMV-specific antibodies shown in Supporting Information Fig. S4) after infection secondary to generalized lymphopenia, altered B cell maturation, or patient age. Regarding impaired specific Ig production, it is known that sepsis triggers immune cell hyperactivity followed, days later, by immune paralysis, which associates with
Figure 4. Humoral response is related to severity in COVID-19 patients. (A) Serum concentration (mg/dl) of IgG, IgA, IgM, C3, C4, and C5a in COVID-19 patients according to their hospitalization period was quantified by nephelometry or ELISA. (B) Fold change of IgG1, IgG3, and IgG4 levels between day 0 and day +10 after admission. Green boxplots correspond to patients with a hospitalization period of less than 15 days (n = 13) and orange boxplots to those hospitalized more than 15 days (n = 24). C5a quantification in orange boxplot corresponds to n = 15. Asterisks indicate significant differences (p-values for Mann-Whitney t-test or Wilcoxon t-test, as appropriate: *p < 0.05, **p < 0.01, ***p < 0.001, ****p < 0.0001). Data are from samples collected over a 6 weeks period and analyzed within 24 h before freezing the serum. For IgG1, IgG3, and IgG4 levels measurements, samples were thawed and assessed within two independent experiments. Boxplots display percentiles 25 and 75 and the median, and the whiskers correspond to percentiles 5 and 95.

a poor patient outcome [19]. Different mechanisms may underlie this process, including dysregulation of T cell subsets [20]. Isotype switching, which results in the production of IgA and IgG antibodies, is a feature of germinal centers in lymphoid follicles following the activation and interaction of specific B cells and Tfh cells. Despite the increase in cTfh cells in COVID-19 patients, cTfh from individuals with moderate to severe disease express higher levels of CCR7, which inversely correlates with Tfh capacity for activating B cells [21] as CCR7 leads to their retention in the T zone of the lymph node, preventing their interaction with B cells in the GC [17].

Recent reports have described specific phenotypic features of cTfh involved in humoral response against SARS-CoV-2 proteins in convalescent COVID-19 patients [22]. Thus, although cTfh specific for spike protein were mainly cTfh17 (CXCR3-CCR6+), neutralizing antibody activities were directly related to the presence of cTfh1 (CXCR3+C-CR6-) and cTfh2 (CXCR3-C-CR6-) functional subsets. We have not studied in detail the functional profile of
Figure 5. Phenotypic features of NK cells from severe COVID-19 patients. (A) Boxplots show quantification by flow cytometry of the proportion (left) and absolute values (right) of the three main functional subsets of NK cells in healthy donors \( (n = 19) \) and a selected group of COVID-19 patients with different severity degree (mild \( (n = 29) \), moderate \( (n = 40) \), and severe \( (n = 15) \)). (B) Boxplot depict CD16 MFI of CD56^dimCD16^+ and CD56^–CD16^+ NK subpopulations in those same individuals. Asterisks indicate significant differences \( (p\)-values for ANOVA Tukey’s contrast test: * \( p < 0.05 \), ** \( p < 0.01 \), *** \( p < 0.001 \), **** \( p < 0.0001 \)). Data are from 19 experiments, with a median of six patients per experiment and day. Boxplots depict percentiles 25 and 75 and the median, and the whiskers correspond to percentiles 5 and 95.

Likewise, C3 and C4 levels were increased in both mild and moderate patients but not in individuals with severe COVID-19, where C3 and C4 remained within the normal values or were even lower. The reasons for these findings include individual variability in C3 and C4 synthesis due to genetic deficiencies or individual genetic polymorphisms [32–34]. Alternatively, a higher C3 and C4 consumption may occur in severe patients by excessive activation of either the lectins pathway or the classical pathway through specific anti-viral antibodies or immune complexes. The selective C4 depletion observed is probably due to the limited amount of C4 in plasma compared to C3, which is one of the most abundant plasma proteins. In addition, a clear correlation between C3 and C4 was found in those patients (data not shown), suggesting a parallel consumption of both proteins which are characteristic of some autoimmune diseases and severe infections [35–38].

Accordingly, we found increased levels of C5a (the activation product of C5) also in patients with severe disease. Similarly, recent reports have demonstrated that C5a and other complement activation products like C5b-C9 are increased in COVID-19 patients [24, 39]. Hence, sustained high C5a concentration in the presence of normal or reduced levels of C3 and C4 would support complement activation in these patients. Quantification of C1q, mannos-binding lectin, and factor B, among others, could further clarify which pathways are responsible for complement activation in COVID-19.

C5a is one of the strongest proinflammatory molecules, since it has chemoattractant activity and activates most leukocytes. In particular, C5a promotes the lung sequestration of myeloid cells [40] and pulmonary dysfunction and exerts procoagulant activity through several mechanisms, including the induction of tissue factor by endothelial cells and neutrophils, as well as the upregulation of plasminogen activator inhibitor-1 in mast cells. In addition, the cytokytically inactive terminal complement complex C5b-9 induces procoagulant activity through platelet prothrombinase and activates endothelial cells to express adhesion molecules and tissue factor [41–44]. In summary, our findings support the idea of complement being involved in the hyperinflammatory syndrome and thrombotic microangiopathies observed in COVID-19 patients.

NK cells are involved in the early immune defense against viral respiratory infections [45]. Actually, several studies from SARS-CoV and MERS infections, either in patients or animal models, had already revealed that these cells play an important role in fighting coronavirus [46–48]. The behavior of NK cells in response to SARS-CoV-2 infection is not unique but similar to that described in other viral infections [49] and in the previous outbreaks of coronavirus-associated SARS pneumonia. NK cell absolute numbers were reduced in patients compared to non-infected donors, with significantly lower counts in severe cases than in moderate or mild patients [50–52]. These authors have found no significant differences either in the proportion of the whole NK population or in their main subsets CD56bright and CD56dim. However, to our knowledge, the CD56-CD16+ NK cell subset has not been analyzed yet in the context of the COVID-19. We have observed that this subpopulation is clearly expanded in severe patients, and that CD16 expression is significantly lower in this subset when compared with healthy donors. This particular CD56-CD16+ population is expanded in some viral infections and demonstrates cytokine activation and ADCC activity in some settings. However, CD56-CD16+ NK cells have been shown to have less functionality and lower expression of natural cytotoxicity receptors in other situations [18, 53, 54]. Compared to peripheral blood, the normal human lung is enriched in NK cells, which present a differentiated phenotype and have the capacity to respond to viral infections [55, 56]. But the persistence of highly active NK cells in the lung may exacerbate inflammation and result in intense and irreversible damage of the airway epithelial cells [57, 58].

Many questions arise from the experimental data provided in this work. Whether the normal levels of C3 and C4 of our severe patients are reflecting a primary or secondary complement immunodeficiency or, on the contrary, excessive activation of complement, is not known. Is the NK CD56-CD16+ subset promoting host defense or mediating tissue injury? Are they contributing to the antiviral response or reflecting a severely compromised innate immune response? At any rate, the increase of cTfh cells and the NK CD56-CD16+ subset, the low levels of total IgG, or the decrease of IgG1 and IgG3 over time that characterize severe patients open new exploratory avenues of research.

Thus, while the immune system is required for protection from SARS-CoV-2 infection, its response, if excessive or sustained over time, like that occurring in COVID-19, may perpetuate both ongoing inflammation and the hypercoagulable state. It is, therefore, necessary to provide more insights related to individual characteristics and the particular kinetics of the host response to SARS-CoV-2, to further understand the pathogenesis of COVID-19 and to decide the appropriate therapy and the treatment timing. This knowledge is of particular therapeutic relevance since it is the basis for clinical trials with the different immune modulators that are currently available including intravenous immunoglobulins, hyperimmune plasma, or complement inhibitors, among others [59–61].

Material and methods

Study design and population

This is a retrospective observational study including 276 consecutive patients with confirmed detection of SARS-CoV-2 RNA, and admitted to the Accident and Emergency Department of the Hospital Universitario La Princesa because of mild to critical COVID-19 symptoms, from February 27 to April 29, 2020.

Data collection

Demographic and laboratory data described in Table 1 were collected from electronic clinical records and included in an anonymized database. Baseline evaluation of immunity was...
performed around the 3rd day of admission (median = 3 days; percentile 25–75 [p25-p75] 2 to 6). A second evaluation was obtained around the 14th day of admission (median = 14 days; p25-p75 12 to 16.5) in a selected group of 37 patients.

SARS-CoV-2 RNA detection

Samples from nasopharyngeal and throat exudates were obtained with specific swabs as previously described [62]. As first-line screening, we performed real-time RT-PCR assay targeting the E gene of SARS-CoV-2, with Real-Time ready RNA Virus Master on Applied Biosystems TM Quant Studio-5 Real-Time PCR System. This assay was followed by confirmatory testing with the assay TaqPath™ COVID-19 CE-IVD Kit RT-PCR Applied Biosystems™ (ThermoFisher Scientific, Waltham, MA USA), which contains a set of TaqMan RT PCR assays for in vitro diagnostic use. This kit includes three assays that target SARS-CoV-2 genes (Orf1ab, S gene, N gene) and one positive control assay that targets the human RNase P RPPH1 gene [63]. Determinations were carried out in an Applied Biosystems™ QuantStudio-5 Real-Time PCR System (CA, USA).

Sample collection and flow cytometry analysis

Peripheral blood samples from 276 COVID-19 patients were obtained in EDTA tubes for flow cytometry assessment around the 3rd day of admission. The distribution of the different leukocyte subsets was characterized by multiparametric flow cytometry within 24 h after extraction following the Guidelines for the subsets. These patients, as well as 19 healthy donors, were studied with an extended panel of multicolor monoclonal antibodies (mAbs): anti-CD4 FITC, anti-igD FITC, anti-CD65 PE, anti-CD27 PE, anti-CD38 PerCP/Cy5.5, anti-CXCR5 AF647, anti-CD19 APC, anti-CD19 PE-Cy7, anti-CD8 APC/H7, anti-CD10 APC/H7, anti-CCR7 BV421, anti-CD16 V450, anti-CD3 V500 from BD Biosciences (USA); and anti-CD20 V450 from Immunostep (Spain).

Samples were incubated for 30 min at room temperature with the respective mAbs. Then, erythrocytes were lysed with FACS lysis solution (BD Biosciences) for 10 minutes and after washing with PBS, samples were analyzed in a FACS Canto II device (BD). At least 100 cells of the less represented subsets were collected and data were analyzed with the FACSDiva and FlowJo Softwares from BD Biosciences. The different leukocyte subsets were assigned according to the strategy showed in supplementary Fig. S1.

Data are expressed as a percentage or absolute number in cells/μl of a given lymphocyte subpopulation. A dual-platform method was used to calculate absolute cell counts. Mean fluorescence intensity (MFI) was employed to compare the level of expression of certain molecules.

Serum concentrations of immunoglobulins and complement proteins

Serum samples were tested by immunonephelometry for total IgG, IgA, IgM, C3, and C4 concentrations (Immage800, Beckman Coulter, California, USA) and for IgG1, IgG3 and IgG4 (Optilite, The Binding Site, Birmingham, UK). C5a quantification was performed with the MicroVue C5a ELISA kit (Quidel, Athens, USA) following manufacturer’s instructions. In addition, 19 serum samples from healthy donors obtained during the same period time were used to determine the variability of Ig, C3 and C4 and C5a levels in normal conditions. The absence of SARS-CoV-2 infection in healthy donors at the time of extraction was confirmed by retrospective determination of specific antibodies. The presence of circulating immunocomplexes was assessed with C1q CIC ELISA Kit (INOVA, San Diego, USA) following manufacturer’s instructions.

Detection of specific antibodies against SARS-CoV-2 and Cytomegalovirus

Nucleoprotein (NP) and the Receptor Binding Domain (RBD) of SARS-CoV-2 were produced and ELISA was performed as described by Martinez-Fleta et al.[65]. 96-Well Maxisorp Nunc-ImmuNo plate was coated with 100 µl/well of recombinant proteins diluted in 0.1 M borate buffered saline (BBS) pH 8.8; NP at 0.5 µg/ml, RBD at 1 µg/ml and incubated overnight at 4°C. Coating solutions were then aspirated, the ELISA plates were washed three times with 200 µl of PBS 0.05% Tween 20 (PBS-T) and blocked with 200 µl PBS-casein (Biorad, 1 × PBS blocker) for 1 h at room temperature. The plates were washed again with PBS-T and 100 µl of patient serum sample diluted in PBS-casein, 0.02% Tween-20, was added and incubated for 2 h at room temperature. The plates were washed again and 100 µl/well of AffiniPure Rabbit Anti-Human IgG (Fcy fragment specific) from Jackson Labs was added and incubated for 1 hour at room temperature. The plates were washed with PBS-T four times and incubated at room temperature in the dark with 100 µl/well of Substrate Solution (OPD, Sigma prepared according to the manufacturer’s instructions) (typically for 3 minutes). 50 µl of stop solution (3M H2SO4) were then added to each well and the OD (at 492nm) of each well was determined using a microplate reader.

Negative controls included wells coated just with blocking buffer and serum samples collected from healthy donors before
2019. The cut-off was established by comparison with the result of a positive serum sample.

Serum samples were also assessed with an anti-CMV/IgG detection kit (Enzygnos, Siemens), following manufacturer’s instructions.

Statistics

Descriptive results were expressed as mean ± SD or median and percentile 25-percentile 75 (p25-p75), as appropriate, while qualitative variables are presented as frequency (n) and relative percentages of patients (%). The unpaired, two-tailed, Student t-test was used to compare two independent groups and the paired Student t-test, to analyze two related samples. One-way ANOVA was employed to compare more than two groups and post hoc multiple comparisons were made with Tukey’s test. Spearman bivariate correlations were performed between serological quantitative markers and cell populations and corrplot R package (available from: https://github.com/taiyun/corrplot) was used for correlation map graphics. Variables in correlation map were reordered using the hierarchical cluster method. The p-values were two-sided and statistical significance was considered when p < 0.05. To analyze the distribution of lymphocytes in COVID-19 patients and healthy donors, an automated clustering and dimensionality reduction were performed using viSNE and FlowSOM tools (Cytobank). Population cells were normalized using log transformation for analysis. Differences in normalized cells between healthy donors and severity groups (adjusted by sex and age) were assessed with a moderated t-test using limma R package. Markers and cell populations and corrplot R package (available from: https://github.com/taiyun/corrplot) was used for correlation map graphics. Variables in correlation map were reordered using the hierarchical cluster method. The p-values were two-sided and statistical significance was considered when p < 0.05.

Study approval

This study was approved by the local Research Ethics Committee (register number 4070) and it was carried out following the ethical principles established in the Declaration of Helsinki. All included patients were informed about the study and gave an oral informed consent because of COVID-19 emergency as proposed by AEMPS (Agencia Española del Medicamento y Productos Sanitarios).

Author contributions

A.A., F.S.M., and C.M.C. developed the research idea and study concept, designed the study, and wrote the manuscript; A.M.J., S.S.A., and A.A.S. designed and conducted most experiments, analyzed the data, and prepared the figures; M.S.N. performed statistical analysis; M.L.T., E.M.G., M.J.C., S.C., H.F., and I.G.A. provided clinical data and peripheral blood samples from the study patient cohorts and critically revised the manuscript. J.M.R.E., J.M.C., H.T.R., and M.V.G provided the reagents for the detection of specific antibodies against SARS-CoV-2. All other authors participated in patient sample processing and clinical data collection.

Acknowledgments: The study was funded by grants SAF2017-82886-R to FS-M from the Ministerio de Economía y Competitividad, and from “La Caixa Banking Foundation” (HR17-00016) to FS-M. Grant PI018/01163 to CMC and grant PI19/00549 to AA were funded by Fondo de Investigaciones Sanitarias, Ministerio de Sanidad y Consumo, Spain. SAF2017-82886-R, PI018/01163 and PI19/00549 grants were also co-funded by European Regional Development Fund, ERDF/FEDER. This work has been funded by grants Fondo Supera COVID (CRUE-Banco de Santander) to FSM, and “Ayuda Covid 2019” from Comunidad de Madrid. We thank Dr. Miguel Vicente-Manzanares for proofreading and English editing of the manuscript. We also thank the immunology service staff for technical support: Víctor López-Huete, Alicia Román, Reyes Lázaro-Tejedor, Alicia Vara-Vega, Montserrat Arroyo-Correa, Manuela Mayo. The Graphical Abstract was created with BioRender.com.

Conflict of interest: The authors declare no commercial or financial conflict of interest.

Peer review: The peer review history for this article is available at https://publons.com/publon/10.1002/eji.202048858.

Data availability statement: The data that support the findings of this study are available from the corresponding author upon reasonable request.
